Multiple episodes of gonorrhea may occur in a single individual in a short period and may be caused by the same strain. The antigenic diversity and ease of altering the antigenicity of both pili and opacity proteins undoubtedly contribute to the insufficiency of the host response in preventing reinfection. Noninvasive mucosal infections elicit production of low-affinity, broadly reactive IgM antibody by IgD⁺, CD27⁺ B cells in a T-cell-independent manner that may partially explain the limited humoral response to typical infections.³⁰⁴ In a mouse model of vaginal infection, gonococci induce T_H17 inflammatory responses, which drive neutrophil influx. T_H1- and T_H2-adaptive specific antibody responses are suppressed by increased production of TGF-β plus enhanced development of T-regulatory cells. TGF-β production is mediated by interaction of Opa proteins with carcinoembryonic antigen related-cellular adhesion (CEACAM) molecules on human cells.²⁰³

Circulating humoral antibody to the infecting strain is present in most persons who have prolonged mucosal colonization with *N. gonorrhoeae*.¹⁸³ Women who develop pelvic inflammatory disease (PID) usually produce bactericidal antibody during the infection. IgA- and IgG-blocking antibodies against some gonococcal antigens appear to block killing of the bacteria mediated by otherwise bactericidal IgG and IgM antibodies.²⁶⁶ Serum antibody responses are greater in patients with invasive disease (e.g., bacteremia or salpingitis).

Secretory IgA antibody is present in the urethral exudate of men with gonorrhea and in the genital secretions of women with gonorrhea.²⁴³ The development of local IgA antibody occurs more rapidly and is more transient than development of the serum bactericidal response. Microbial IgA1 protease is not required for infection but may play a role in reinfection.

A cellular immune response to gonococcal antigens in patients with uncomplicated gonorrhea has been demonstrated in vitro.¹⁹⁶ The significance of this response in controlling or preventing infection is unknown.

PERINATAL GONOCOCCAL INFECTIONS

Since the 1970s, health clinics have encouraged the routine screening of sexually active women for gonorrhea, especially during pregnancy. Adolescent girls have a higher prevalence of gonorrhea than do older women of child-bearing age. This probably translates into higher rates of gonorrhea in pregnant adolescents. Rates of gonococcal infection in neonates reflect the frequency of infection in pregnant women. Recognition of gonorrhea early in pregnancy identifies a population at risk who should be monitored sequentially for reinfection throughout pregnancy.¹⁷⁵

The spectrum of infection with *N. gonorrhoeae* appears to be similar in pregnant and nonpregnant women. Most are asymptomatic. Pharyngeal infection seems to occur more commonly during pregnancy, perhaps reflecting altered sexual practices. One study reported that 39% of patients with *N. gonorrhoeae* at any site had concurrent involvement of the pharynx and that 30% had pharyngeal infection as the sole manifestation.⁷⁸ In adolescent girls, pregnancy and menstruation are associated with disseminated disease.¹⁵⁸

Gonorrheal infection puts both the mother and infant at risk for the development of other forms of gonococcal disease. Pregnant women, including those of adolescent age, have an increased risk for the development of gonococcal septic arthritis, and most such cases occur during the third trimester or in the immediate postpartum period.^{39,158}

Gonococcal PID and acute salpingitis may complicate the pregnancy of an infected woman.¹²³ When these complications occur during the first trimester there is a high rate of fetal loss. Untreated gonorrhea late in pregnancy can lead to postpartum fever in the mother.¹⁷⁰

Hazards to the fetus posed by maternal gonorrhea include septic abortion, perinatal death, prematurity, perinatal distress, and premature

rupture of membranes. Prolonged rupture of membranes, premature delivery, chorioamnionitis, funisitis, and a clinical diagnosis of sepsis occur frequently in infants with *N. gonorrhoeae* detected in the gastric aspirate during delivery.^{6,105,108,148,273} Table 89.2 tabulates the proportions in six studies of infants born to infected mothers who experienced these problems.

Gonococcal Ophthalmia Neonatorum

Epidemiology

The increased risk for ophthalmia neonatorum among infants born to women with vaginal discharge has been recognized for centuries. Recommendations for flushing the eyes of a newborn commonly were given before the 20th century.²¹⁶ In the late 1800s, Neisser helped establish the relationship between the gonococcus and neonatal ophthalmia.

By 1881, Dr. Carl Sigmund Franz Credé recognized that asymptomatic disease in the mother was a potential source of infection.⁸⁴ Gonorrhea was highly prevalent in Europe; gonococcal ophthalmia neonatorum (GON) was occurring in approximately 10% of newborns in major cities. The infection was the cause of a large proportion of admissions to schools for the blind.¹⁶ Credé described the technique of instillation of 2% silver nitrate into the infant's conjunctival sac, which remains one method recommended for preventive procedures today.

By 1930, most states in the United States required that all newborns receive silver nitrate prophylaxis (i.e., the Credé procedure). GON decreased as a cause of admission to schools for the blind in the United States, from an average of 24% from 1906 to 1911 to 0.5% from 1951 to 1955.

The worldwide decline in adult gonorrhea in the 1950s probably contributed to the decreased recognition of disease in newborns during that period. The incidence of GON rose in the 1960s and 1970s along with the increased incidence of gonorrhea in the general population and was very high in some developing nations.¹⁹³ In Los Angeles, the rate rose from nine per 100,000 live births in 1957 to 1958 to 56 per 100,000 live births in 1962 to 1963. In a New York hospital between 1970 and 1973, a rate of 145 per 100,000 births was reported; in a hospital in North Carolina during 1969 and 1970, a rate of 265 per 100,000 live births was proved by culture.³⁰³ In the late 1970s and 1980s, GON again subsided in developed countries but has remained a problem in underdeveloped nations.

Factors associated with higher rates of GON include lower socioeconomic class of the mother and longer duration of rupture of membranes before delivery.¹⁰ An increased incidence of GON in infants of unwed mothers and mothers who have not had prenatal care also may exist.²⁹⁹ Previous treatment of gonorrhea during pregnancy also is associated with an increased incidence of GON.¹⁷⁵ The incidence of prematurity in infants with GON often is reported to be higher. Premature rupture of membranes appears to increase the risk for GON.

Prevention

In the United States, prophylaxis for GON is recommended for all infants immediately after birth and is required by law in most states.³²⁷ Prophylaxis regimens using a 1% solution of silver nitrate, 1% tetracycline ointment, or 0.5% erythromycin ophthalmic ointment are equally

effective. In the United States, erythromycin 0.5% ophthalmic ointment is the only one of these agents available for prophylaxis of GON. Single-dose units are preferred over multidose tubes. One unit should be instilled into the eyes of every neonate as soon as possible after delivery. Instillation may be delayed for as long as 1 hour to facilitate parent-infant bonding.

The efficacies of tetracycline and erythromycin preparations in the prevention of tetracycline-resistant *N. gonorrhoeae* ophthalmia are unknown.²⁴⁴ Both probably are effective because of the high concentration of drug in these preparations.

Silver Nitrate and Gonococcal Ophthalmia Neonatorum

Numerous studies have compared the efficacy of silver nitrate and no prophylaxis or prophylaxis with another agent in the prevention of GON.^{67,226,274} Such studies consistently showed lower rates of GON in treated versus untreated infants. Decreased frequency of blindness from GON in the population during the past half century, even during periods of increased rates of gonorrhea in women of child-bearing age, further supports the benefits of silver nitrate prophylaxis.

In a randomized trial of Kenyan infants born to mothers with gonorrhea reported in 1988, rates of GON were 42% in the control group, 7% in the group treated with 1% silver nitrate (83% reduction), and 3% in the group treated with 1% tetracycline (93% reduction). The two treatment arms were not statistically different.¹⁹⁵ In a randomized trial in the United States involving infants born to women without gonococcal infection, infants treated with 1% silver nitrate had a 39% lower rate (statistically significant) of conjunctivitis of any type in the first 2 months of life than did infants who received no prophylaxis. Infants treated with 0.5% erythromycin ointment in this trial had a 31% reduction in contrast to control infants, but this result was not statistically significant.¹⁹

The major advantages of the use of silver nitrate for prophylaxis are the lack of allergic potential, the absence of development of bacterial resistance to the compound, and very low cost. Two outbreaks of erythromycin-resistant staphylococcal conjunctivitis in newborn nurseries have been associated with the use of erythromycin eye ointment as ocular prophylaxis, but the outbreaks remitted when silver nitrate was substituted. Disadvantages include the occurrence of conjunctival irritation with associated development of exudate in many neonates. Failure of silver nitrate prophylaxis (as well as other agents for prevention of GON) does occur. Improper administration of silver nitrate such that the solution does not reach the conjunctival sac, irrigation performed too quickly after instillation, and inadvertent omission of prophylaxis can lead to apparent failure. When gonococcal infection of the eye has become established before birth, silver nitrate is not expected to prevent further progression. The increased risk for GON associated with premature rupture of membranes is due to exposure to and establishment of infection before actual delivery. In some cases of premature rupture of membranes, clinically apparent GON can be present at the time of birth.

Despite these problems, the use of 1% silver nitrate remains a widely accepted, carefully evaluated, and safe form of GON prophylaxis. The occasional failure of silver nitrate prophylaxis emphasizes that it is

preferable to prevent GON through identification and treatment of pregnant women.

Clinical Features

The newborn eye is subject to colonization with numerous bacterial organisms that cause infections that usually are clinically mild, non-progressive, and characterized by conjunctival discharge. The bacteria most commonly associated with conjunctival discharge are *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Neisseria cinerea*, *Klebsiella pneumoniae*, enterococci, and *C. trachomatis*.^{100,192} Viral causes include herpes simplex virus and adenoviruses. In contrast, infection of the eye of a newborn with *N. gonorrhoeae* results in disease of a severity that, despite frequently being mild, can be rapidly destructive and lead to scarring and blindness. The chemical conjunctivitis that can result from silver nitrate prophylaxis typically starts within 6 to 24 hours after administration and disappears within 24 to 48 hours.

Colonization during delivery is followed by an incubation period of 2 to 5 days and usually less than 3 days, but cases occasionally may be recognized for 2 to 3 weeks after delivery.¹²¹ A discharge typically develops that initially is watery but usually becomes thick and mucopurulent within a short time and may contain blood (Fig. 89.5). The disease generally is bilateral. Early findings include prominent edema of the conjunctivae and lids, followed by edema and later ulceration of the cornea or spread to wider areas in severe cases. Rapid arrest of the disease is essential because the degree of corneal involvement determines whether vision will be preserved. Some cases are self-limited and have benign outcomes, and occasional cases of asymptomatic GON have been discovered during routine screening.²⁵⁵ Perforation of the globe and panophthalmitis can result from extensive local disease. The conjunctivae may serve as a portal of entry for gonococcal septicemia, arthritis, or other manifestations of invasive disease, but such events seldom occur.

FIG. 89.5 Gonococcal ophthalmia neonatorum. The usual clinical finding is bilateral conjunctivitis that becomes progressively purulent if untreated. (From Gutman LT. Gonococcal infections. *Semin Pediatr Infect Dis.* 2005;16:4.)

A presumptive diagnosis may be made by demonstrating typical gram-negative diplococci by Gram stain of conjunctival exudate. Because other organisms also may cause exudative infection of the conjunctivae, laboratory confirmation of the diagnosis of GON depends on culture results of *N. gonorrhoeae*.

Invasive disease rarely occurs in association with GON, but neonates with clinical evidence suggestive of GON should be evaluated for disseminated disease. The evaluation should include a thorough physical examination, especially of the joints. Exudate from the eyes or other sites of apparent local infection should be sent for Gram stain and culture on appropriate media.

Current recommendations in the United States are to obtain cultures of blood, eye discharge, and other potential sites of infection, including CSF.³⁴³ The absolute necessity of obtaining CSF for analysis and culture in otherwise well-appearing neonates is not certain but likely prudent. Neonates with GON generally should be hospitalized as part of initial management.

Testing for *C. trachomatis* infection of the conjunctiva also should be performed.

Gonococcal Scalp Abscess and Other Local Infections

Gonococcal infections of scalp wounds occur especially after fetal monitoring electrodes have been used on infants born to infected mothers.⁸⁸ The lesions may produce extensive local inflammatory disease and necrosis and can be a focus for disseminated infection. A scalp wound in a neonate should be cultured for gonococci, as well as other likely pathogens, which include *Staphylococcus* spp., group B streptococci, *H. influenzae*, and gram-negative enteric flora. Herpes simplex also may be present in areas of injury to the scalp of newborns. Overall approximately one in 200 births that are monitored with fetal scalp electrodes are complicated by infection at the monitoring site.²⁵⁴

Neonatal gonococcal vulvovaginitis, proctitis, rhinitis, funisitis, and urethritis have been described but are rare.¹⁴⁴ Gonococcal colonization of the oropharynx, gastric fluid, or both occurs relatively frequently in perinatally exposed infants, however. Pharyngeal colonization is present in as many as 35% of neonates who have GON.¹¹⁹ A summary of selected studies on the incidence of neonatal gonococcal colonization and disease in exposed infants is presented in Table 89.3.

Infants with localized gonococcal infection other than GON should have cultures obtained of blood, CSF, and the site of infection, if feasible. They should be hospitalized pending the availability of culture results.

Systemic Disease in the Neonate

Disseminated disease occurs in 1% or fewer of infants who are perinatally exposed to gonococcal infection¹² (see Table 89.3). Septic arthritis is the most common form of disseminated gonococcal infection in neonates. Gonococcal arthritis of the newborn was described extensively between 1900 and 1930,^{76,77,334} and recent case reports suggest that the disease remains similar. Clinical findings usually become evident when the infant is 1 to 4 weeks old. Although a few infants with gonococcal arthritis will have evidence of GON or other sites of mucosal or skin infection at the time of onset of arthritis, most do not. Concurrent gonococcal arthritis in both mother and newborn infant has been described.¹³⁶

The signs and symptoms of gonococcal septic arthritis are similar to those of joint infection caused by other microbes in the neonatal

TABLE 89.3 Incidence of Neonatal Gonococcal Disease in Exposed Infants			
Site of Neonatal Infection	Rate of Positive Cultures (%)	Population	References
Conjunctiva	0–10	Exposed infants who underwent silver nitrate ocular prophylaxis	4, 10, 105,193
	2–48	Exposed infants who had no ocular prophylaxis	119, 188, 274
Orogastric fluid	26–40	Infants of infected mothers	105, 148
Oropharynx	35	Infants with gonococcal ophthalmia	193
Disseminated disease as a proportion of all neonatal gonorrhea	0–1 (rare)	Reported series of neonatal gonococcal disease	105, 117, 119, 323, 332

period, including a predominance of polyarticular involvement. Infection most frequently involves the ankles, knees, wrists, and hands.⁷⁶ The hip may be infected with minimal signs other than pseudoparesis. Involvement of a joint may include suppurative arthritis, inflammatory disease of the periarticular structures, and tenosynovitis. Leukocytosis usually occurs, and most infants have a positive culture and compatible Gram stain results from the synovial fluid of the involved joint.¹²⁸

Prompt drainage of septic hips, along with initiation of antimicrobial therapy, is necessary because of the risk for development of aseptic necrosis of the femoral head. Long-term dysfunction from gonococcal infection of other joints seldom occurs.^{77,144,160,189}

Although gonococcal sepsis can develop in neonates with or without associated septic arthritis, the bacteremic phase of spread to the joints from the initial sites of infection generally is typically clinically silent. Premature infants seem to be more at risk for the development of sepsis with bacteremia than are term infants. Meningitis is an exceedingly rare manifestation of neonatal gonococcal infection.^{31,144,148}

GONOCOCCAL DISEASE BEYOND THE NEONATAL PERIOD

Lower Genital Tract Infection in Prepubertal Girls

Gonococcal vaginitis or vulvovaginitis is the most common form of gonorrhea in prepubertal girls beyond the neonatal period. In contrast to that of postpubertal females, the anestrogonic vaginal mucosa of prepubertal girls creates an alkaline environment that is colonized and infected more readily with *N. gonorrhoeae*. Infection of the endocervix, urethra, paraurethral and Bartholin's glands, and upper genital tract occurs only rarely.

Gonococcal vaginitis in prepubertal girls almost always is symptomatic, with vulvar erythema and a profuse vaginal discharge (Fig. 89.6). The girl may complain of dysuria, urinary frequency, vulvar discomfort, or pain while walking.^{232,294,296} Asymptomatic cases are uncommon.

Signs and symptoms should resolve promptly within a few days after treatment is initiated, but acute manifestations may persist for several weeks if the child is not treated. The natural course of disease is for the inflammation to subside and the discharge to become scant and seropurulent. Infection may resolve spontaneously but occasionally may persist until the girl reaches puberty.

Prepubertal vulvovaginitis can be caused by numerous irritative and infectious agents, including pinworms, foreign bodies, group A streptococci, *Neisseria meningitidis*, *Neisseria sicca*, and *Moraxella catarrhalis* (see Chapter 42). Vulvovaginitis can mimic urinary tract infection, and

FIG. 89.6 Profuse, purulent vaginal discharge in an 18-month-old girl with gonococcal vulvovaginitis. Gonococcal infections in prepubertal children are almost always the result of sexual abuse. (From American Academy of Pediatrics 2012 Red Book Collection.)

pyuria can be seen on urinalysis with gonococcal and other causes of vulvovaginitis.^{120,202}

Although ascending infection seldom occurs in this age group, it may result in salpingitis or peritonitis. One study found that 10% of young girls with gonorrhea had signs compatible with peritonitis, including fever, diffuse abdominal pain, leukocytosis, and decreased bowel sounds.⁴⁵ Salpingitis and periappendicitis may cause findings similar to those of appendicitis.¹¹

In children with gonorrheal infection of the genitourinary tract resulting from sexual abuse concomitant anorectal and tonsillopharyngeal colonization are common.²³⁷

Lower Genital Tract Infection in Postmenarchal Females

Gonococcal infections in adolescent girls are similar to those in adults. The endocervix is the primary site of urogenital infection, although the external genitalia, urethra, vulvar mucosa, and vestibular glands also may be infected. Symptoms of acute infection usually begin 3 to 5 days after exposure with the development of a profuse, purulent vaginal discharge. The vulvar tissues are inflamed, with resultant pruritus and a burning sensation. Urethritis often is present initially and can lead to dysuria with urinary frequency and urgency. Urethral discharge can be seen but is much less prominent than in males. A purulent discharge from the vestibular and paraurethral glands also may be noted.

The endocervical mucosa is edematous, inflamed, and often friable (Fig. 89.7). A profuse yellow-green discharge is present and detaches easily from the surface. The zone of endocervical ectopy that normally is present in as many as 50% of adolescents may appear bright red, does not bleed easily when touched with swabs, and should not be mistaken for cervicitis. Ectopy that appears swollen and friable suggests cervicitis. Nabothian inclusion cysts (transparent and grayish) also are normal findings.

Infection of Bartholin's (major vestibular) gland or paraurethral (Skene's) gland ducts may develop during acute gonorrhea. Bartholin's gland abscesses appear as large, circumscribed painful swellings of the dorsal aspect of the labium minus (Fig. 89.8). This occurs in about 5% of females with endocervical gonorrhea.²⁶² Paraurethral duct abscesses appear as small painful swellings in the urethrovaginal septum and may cause dysuria. Rupture into the urethra can create a urethral diverticulum. Bartholin's gland or paraurethral duct abscesses should be incised and drained.

If the gonococcal infection goes untreated, the acute symptoms generally subside in 8 to 10 weeks. In a cohort of 387 adolescents 14 to 17 years of age who were evaluated by weekly quantitative cultures, 16 developed acute infection. Microbial load did not correlate with genitourinary symptoms.³¹⁵

Persisting acute symptoms are more likely to represent reinfection than chronic infection. Chronic urethritis, thickening of the vestibular glands and paraurethral ducts, and chronic cervicitis can occur. A

FIG. 89.7 Colposcopic view of cervix showing eroded ostium resulting from gonococcal infection. (From American Academy of Pediatrics 2012 Red Book Collection.)

FIG. 89.8 Acute Bartholin's duct abscess.

secondary nonspecific vaginitis can develop as a result of irritation of the mucosa from persisting profuse endocervical discharge.

Mucopurulent cervicitis can be caused by *N. gonorrhoeae*, *C. trachomatis*, *Gardnerella vaginalis*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and group B streptococci. The overlap in clinical manifestations of infections caused by these microbes and the frequency of infection by two or more simultaneously preclude establishing the diagnosis by clinical findings alone.

Adolescents may be unaware of their infection, especially if they have a preexisting profuse discharge as a result of nonspecific vaginitis or trichomoniasis. Early recognition and treatment of lower genital tract gonococcal infection may prevent extension to and complications of upper genital tract infection. Therefore sexually active adolescent females should be examined for gonococcal infection as part of their routine health care.^{153,280}

A review of reported complications in 1232 cases of gonococcal vaginitis in the pre-antibiotic era revealed that 35% had urethritis, 19% had proctitis, and 6% had peritonitis.²⁰

Urinalysis may provide clues to gonococcal infection in some cases. In a cross-sectional study of 296 sexually active females 14 to 22 years of age, gonorrhea or trichomoniasis was present in 65% who had sterile pyuria.¹⁶⁴

Upper Genital Tract Infection in Postmenarchal Females

PID will develop in 10% to 17% of females with endocervical gonococcal infection. Conditions encompassed by the term *pelvic inflammatory disease* include endometritis, parametritis, salpingitis, oophoritis, tubo-ovarian abscess, and pelvic peritonitis. PID can be caused by a variety of bacteria. Anaerobes, including *Bacteroides*, *Peptococcus*, and *Peptostreptococcus* spp., are the organisms usually recovered. *N. gonorrhoeae* is present in 25% to 50% of cases, similar to the proportion of cases from which *C. trachomatis* is recovered. Coliform organisms, *G. vaginalis*, *M. hominis*, *U. urealyticum*, and various streptococcal species also may be involved. PID develops when these organisms are able to ascend into the uterus, fallopian tubes, and beyond from the lower genital tract. Multiple species may be involved in a single episode. Gonococcal PID

often occurs during or just after menses.^{110,158} Identification of the specific microbial cause or causes of PID is complicated by the difficulty of obtaining fallopian tube specimens before initiating therapy.

Common findings in PID include an acute onset of lower abdominal pain with tenderness, fever, tenderness on lateral motion of the cervix, adnexal tenderness that generally is bilateral, and adnexal fullness. Vaginal discharge, urinary symptoms, and irregular vaginal bleeding also may be present. In moderate to severe cases, abdominal pain frequently is bilateral, exacerbated with movement, and continuous. Nausea, vomiting, marked abdominal tenderness, an abdomen that appears tense, and fever exceeding 39°C (102.2°F) may be present. Such patients often appear to be ill and may have tachycardia consistent with the height of fever.²⁹¹ Leukocytosis and elevated erythrocyte sedimentation rates are common findings. Alternatively, PID may be clinically silent or cause only mild pain without discernible tenderness, vaginal discharge, or leukocytosis. Such mild cases can go unrecognized by patients and physicians.

Establishing the diagnosis of PID may be difficult, and the differential diagnosis includes numerous other lower abdominal conditions, such as appendicitis, ectopic pregnancy, cholecystitis, mesenteric adenitis, pyelonephritis, and septic abortion. Sonography and pregnancy testing may be helpful in diagnostic decision making. No single symptom, sign, or laboratory finding is sensitive and specific for the diagnosis of PID. Combinations of findings can improve the sensitivity but do so at the expense of reduced specificity, and vice versa.

Initiation of empirical therapy for PID should be considered if the minimal criteria of lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness all are present and no other cause for these findings is readily apparent. More elaborate evaluation may be needed in some cases because incorrect diagnosis and management might lead to unnecessary morbidity. Additional criteria that support the diagnosis of PID include an oral temperature higher than 38.3°C (101°F), an abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, increased C-reactive protein level, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*. Some cases may require pursuit of definitive criteria for diagnosing PID, which include histopathologic evidence of endometritis on endometrial biopsy, transvaginal or abdominal ultrasonography or other imaging studies that show thickened fluid-filled fallopian tubes with or without free pelvic fluid or a tubo-ovarian abscess, and laparoscopic abnormalities consistent with PID.¹⁷¹

The outcome for fertility probably is improved with prompt and vigorous therapy. Hospitalization is recommended when the patient is pregnant, a surgical emergency (e.g., ectopic pregnancy or appendicitis) cannot be excluded, when compliance with or tolerance of an outpatient treatment regimen cannot be ensured (e.g., presence of nausea or vomiting), when the illness appears to be severe (e.g., presence of high fever, pelvic or tubo-ovarian abscess, overt peritonitis, or sepsis), or when the patient is immunocompromised or has failed to respond to outpatient therapy. All courses of therapy should include treatment that is appropriate for *C. trachomatis* and other causes of PID, in addition to *N. gonorrhoeae*.³⁴³

Complications of PID include tubo-ovarian abscess, perihepatitis (Fitz-Hugh-Curtis syndrome), future ectopic pregnancy, and infertility. Perihepatitis is characterized by right upper quadrant abdominal pain that may radiate to the shoulder. Nausea, fever, and other signs and symptoms of PID may be present as well. Leukocytosis occurs commonly, and liver enzymes are elevated in some cases. The differential diagnosis of perihepatitis includes pleuritis, cholelithiasis, subphrenic abscess, and perforated ulcers.²⁰¹

An estimated 15% of women may become sterile after a single episode of PID and 50% after three infections. Because of scarring and fibrosis in the fallopian tube, patency is compromised and fertility is jeopardized.^{51,110,111} PID in adolescents is particularly likely to result in infertility and ectopic pregnancy (Fig. 89.9), and PID is the single most common cause of infertility in young women.⁴¹ Between 1970 and 1980, the rate of ectopic pregnancies per 1000 live births increased from 4.8 to 14.5, and between 1975 and 1981, the rate of hospitalization of females 15 to 19 years of age for salpingitis was four per 100,000.³³² These increases correlated with rising rates of gonococcal infection in the affected

populations. Data from several studies of gonococcal disease in adolescents are presented in Table 89.4.

Risk factors for the development of PID include young age at the time of acquisition of gonococcal disease or other STIs, a history of previous PID, multiple sexual partners, and the use of an intrauterine device (IUD) for contraception. The immature cervix may be at particular risk for progression to upper tract disease.²⁹⁸ Disseminated gonococcal infection may accompany asymptomatic infection of an IUD,⁷⁴ and the rate of acute PID in those who use IUDs may be increased.

Genital Tract Infection in Males

Gonococcal urethritis in prepubertal boys is a less frequent event than vaginitis in girls because of gender differences in rates of sexual abuse. As in girls with gonorrheal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is a frequent finding.²³⁷

Urethritis is the primary manifestation of gonococcal infection in males of all ages beyond the neonatal period (Fig. 89.10). Even in young boys, the disease usually is symptomatic and resembles gonococcal urethritis in men.^{83,122} Dysuria, purulent discharge, or both develop 2 to 7 days after exposure. Patients generally are afebrile. Purulence typically is greater than with nongonococcal urethritis, but symptoms often are mild enough that patients (or their parents) may delay seeking medical care for weeks. Associated inguinal adenopathy occurs rarely.

At least 5% of cases of gonococcal urethritis in males are asymptomatic, and asymptomatic infection can occur at all ages. Asymptomatic pyuria is a manifestation with which the pediatrician should be familiar.⁸⁹ It may be the only finding in some cases and should raise suspicion of gonococcal or chlamydial infection in boys who may have been sexually abused or in sexually active adolescent males.

Males with asymptomatic infection are a major reservoir for transmission to their sexual partners. Untreated male urethral infection may persist for as long as 6 months.

Complications of gonococcal infection in males now occur much less frequently than in the pre-antibiotic era. Epididymitis is the most common complication. Unilateral swelling, pain, and erythema in the posterior aspect of the scrotum are the usual features. Fever may occur. If untreated, the infection may progress to involve the ipsilateral testis. Hydrocele may result from secretion of fluid into the potential space of the tunica vaginalis. Epididymitis can lead to testicular infarction, abscess, infertility, prostatitis, paraurethral abscesses, and penile lymphangitis, but these local complications are rare findings. Perihepatitis in males has been described but occurs extremely infrequently.¹⁹¹

Disseminated Disease

Dissemination requires invasion of the bloodstream from local infection of the mucous membranes of the genital tract, rectum, pharynx, or conjunctiva. Bacteremia then can lead to infection of other sites. The risk for dissemination in children after mucosal infection appears to be higher than the 1% to 3% rate in adults. Dissemination in adults seems to be more common with asymptomatic infections, many of which are caused by AHU[−] gonococcal strains.¹⁸⁵ The frequency of deficits in the complement system associated with disseminated disease in children is unknown.

As in neonates, gonococcal arthritis is the most common form of disseminated disease in older children, adolescents, and adults. The ankles, knees, wrists, and hands are involved most frequently. The clinical findings are not distinct from those of other microbial causes of septic arthritis. Polyarticular involvement occurs less frequently than in neonates.⁸¹ Gram stain and synovial fluid cultures often are negative.

FIG. 89.11 Skin lesion typical of the arthritis-dermatitis syndrome of disseminated gonococcal infection: necrotic pustule with an erythematous halo overlying proximal phalanx of index finger. (Courtesy Daniel P. Krowchuk, MD.)

Therefore empirical coverage for *N. gonorrhoeae* must be considered when septic arthritis develops in a sexually active adolescent or a child who may have been sexually abused.

Typically the patient has a single most severely affected joint, and associated myositis and tenosynovitis may be prominent findings. Gonococcal arthritis in older children and adolescents resembles that in adults and may be accompanied by cutaneous lesions (Fig. 89.11).⁴ Osteomyelitis rarely occurs but has been reported in all age groups, usually in association with septic arthritis.⁸

Treatment of gonococcal arthritis depends on prompt recognition of the disease. Cultures of all mucous membranes (i.e., nasopharyngeal, rectal, vaginal or endocervical, and conjunctival), blood culture, and aspiration of the involved joint should be performed. The local signs of gonococcal arthritis may not respond to antibiotic therapy for several days. Serial needle aspiration rather than open drainage usually is sufficient for relief of pain and recovery without sequelae (the hip may be an exception).

Gonococcemia is clinically silent generally but can cause a syndrome of migratory polyarthralgia, fever, and rash that precedes the onset of arthritis by several days to a week. The symptomatic course normally is only mild to moderate in severity. Blood cultures often are negative by the time care is sought. Gonococcemia-related symptoms may resolve after several days, even without treatment. Rare cases can resemble meningococcemia with purpura and fulminant sepsis with disseminated intravascular coagulopathy. These cases sometimes can be fatal.²⁴⁸

The skin lesions associated with gonococcemia usually are pustules on an erythematous base (see Fig. 89.11), but petechiae, papules, and hemorrhagic bullae can develop. Skin lesions in conjunction with septic arthritis also has been referred to as the arthritis-dermatitis syndrome. The lesions usually arise on the extremities and are fewer than 20 in number. Low-grade fever is most common, but high fever with shaking chills may occur. Tenosynovitis is present in a fourth of these patients. Leukocytosis, pyuria, and elevated liver enzyme test results may be seen. The resultant septic joints generally become clinically apparent during the second week after the onset of disseminated infection.

Anorectal Gonorrhea

Gonococcal anorectal infection (proctitis) frequently is asymptomatic but can be associated with pruritus, tenesmus, purulent discharge, or rectal bleeding. Rectal infection can occur as a result of rectal intercourse or inoculation from vaginal secretions. Approximately 40% of females with genital gonococcal infection have positive anorectal cultures. Rectal infection is an unusual finding in males who have not engaged in rectal intercourse.³⁰⁸

Pharyngeal Gonorrhea

Pharyngeal gonococcal infection in all age groups beyond the neonatal period is acquired by orogenital contact. Pharyngeal gonorrhea may be asymptomatic, without evidence of inflammation, or may cause an exudative tonsillopharyngitis that can mimic group A streptococcal or viral infection. Cervical adenopathy may be present in some cases. In sexually abused children, the pharynx may be the only site of infection. It may be the sole culture-positive site in some cases of disseminated

gonococcal infection, and pharyngeal infection possibly is a factor predisposing to dissemination. Pharyngeal infection usually resolves spontaneously within 10 to 12 weeks but should be treated when recognized.^{1,41,64,82,140,237,245,297,337,341} In a recent study of 14- to 21-year-old females hospitalized in a children's hospital or seeking care in a public health clinic, pharyngeal gonorrhea prevalence among adolescents was 3.5% and 6.8%, respectively.¹²⁴

Conjunctivitis Beyond Infancy

Gonococcal ophthalmia occasionally is seen in children and adults. Direct inoculation of the eye can occur as a result of transmission of fomites from infected persons. Clinical findings typically include a profuse purulent discharge, chemosis, eyelid edema, keratitis, and fever. The initial ocular discharge may be watery before turning purulent. The acute phase may mimic orbital cellulitis. Untreated infection, as with neonates, can lead to corneal opacification, ulceration, and rupture of the globe with resultant visual loss. Some cases may be minimally symptomatic, with a low-grade inflammatory response followed by spontaneous resolution.^{197,202,255}

Other Forms of Gonococcal Disease

Gonococcal meningitis is a rare condition that may occur with or without associated signs of gonococcemia or septic arthritis. Pyomyositis of the biceps and soft tissue abscesses remote from the genital area have been reported. A gonococcal abscess arising in an area of blunt trauma to a hand has been described in an adolescent with associated endocervical infection.¹³⁰ An abdominal wall abscess resulting from *N. gonorrhoeae* infection in a 22-month-old male child without other foci of infection has been described.¹⁰¹ Ventriculoperitoneal shunt-associated infection, endocarditis, and myocarditis caused by *N. gonorrhoeae* have been reported in adults and can be expected to occur occasionally in children and adolescents.¹⁵⁸ These manifestations of gonococcal infection seldom are seen in children.

DIAGNOSTIC TESTING

Isolation of *N. gonorrhoeae* in culture remains important for diagnosing gonococcal infection, but nonculture, DNA-based tests have become widely used in recent years. Serologic tests based on complement fixation, latex agglutination, enzyme-linked immunosorbent assays, and other techniques have been developed, but the sensitivity of these methods is only about 70%. These methods are limited now to studies of immune response and pathogenesis.^{157,161,281}

The Centers for Disease Control and Prevention (CDC) also has defined three levels of diagnosis based on clinical and laboratory findings. They are more stringent than the case definitions used for public health surveillance. A *suggestive diagnosis* is defined by presence of mucopurulent endocervical or urethral exudate and sexual exposure to a person with gonococcal infection. A *presumptive diagnosis* requires two of three criteria: (1) typical gram-negative intracellular diplococci on Gram stain of urethral exudate from males or endocervical secretions; (2) growth of apparent *N. gonorrhoeae* from such specimens on culture medium, defined as typical colonial morphology, positive oxidase reaction, and typical gram-negative morphology; and (3) detection of *N. gonorrhoeae* by a nonculture laboratory test. A *definitive diagnosis* requires (1) isolation of *N. gonorrhoeae* from clinical specimens by culture, as in the second criterion for a presumptive diagnosis, and (2) confirmation of identity by biochemical, enzymatic, serologic, or nucleic acid testing.⁵⁹

A diagnosis of *N. gonorrhoeae* infection at any site should prompt evaluation for the presence of other common STIs, if not already done (see Chapter 42).²⁷²

Culture

In adults, culture of clinical specimens is 80% to 95% sensitive when promptly inoculated and incubated. Cultures of adult male urethral specimens, blood, and other normally sterile body sites tend to have sensitivities in the higher range.¹⁶¹ Because false-positive cultures with appropriate laboratory confirmation are not thought to occur, specificity and positive predictive values are 100%. Culture in adolescents and children probably has sensitivity similar to that of adults.

TABLE 89.5 Treatment of Gonococcal Infections in the Neonatal Period

Disease Category	Treatment Regimen	Comments
Infants born to mothers with gonococcal infection or Gonococcal ophthalmia neonatorum (GON) or other focal sites of infection (i.e., rectum, pharynx, vagina, urethra)	Ceftriaxone 25–50 mg/kg IV or IM, not to exceed 125 mg (single dose) ^{a,b,c}	Infants with GON should receive eye irrigation with saline solution immediately on recognition and at frequent intervals subsequently until the discharge is eliminated
Disseminated gonococcal infection (septic arthritis, sepsis, meningitis) or scalp abscess	Ceftriaxone 25–50 mg/kg IV or IM once daily for 7 days (10–14 days for meningitis) or Cefotaxime 25 mg/kg IV or IM every 12 h for 7 days (10–14 days for meningitis)	Cefotaxime is preferred for infants with hyperbilirubinemia who require more than a single dose of therapy If meningitis is present, higher or more frequent doses in the recommended ranges may be needed

IM, Intramuscularly; IV, intravenously.

^aIf ceftriaxone is unavailable or contraindicated, cefotaxime, 100 mg/kg IV or IM (single dose) is an alternative.

^bTopical agents alone are inadequate and unnecessary when recommended systemic antibiotics are given.

^cFor GON, some experts prefer to continue parenteral therapy with one of these agents until blood (with or without cerebrospinal fluid) cultures have been negative for 48 to 72 hours.

Data from Workowski KA, Bolan GA. Sexually Transmitted Diseases Treatment Guidelines, 2015. *MMWR Recomm Rep*. 2015;64:1–137. For potential updates to these recommendations, see <http://www.cdc.gov/std/gonorrhea/treatment.htm>.

The use of selective media such as modified Thayer-Martin is required for culture of endocervical, rectal, and pharyngeal specimens to suppress contaminating flora. Selective or nonselective media (chocolate agar) can be used with equal sensitivity for male urethral cultures. Plating of specimens on both types of media may improve the sensitivity, but the incremental yield is small and probably not cost-effective for routine practice.^{29,87,263}

Gonococcal colonies become evident on agar plates within 24 to 48 hours after inoculation. Isolates are considered presumptively positive if Gram stain shows gram-negative diplococci and colonies are oxidase-positive. Further testing that demonstrates the gonococcal phenotypic pattern of acid production from selected carbohydrates or a positive result by a nucleic acid method, or both is required for confirmation as *N. gonorrhoeae* (Table 89.5).⁶³

Gonococci do not tolerate drying, so clinical specimens must be plated onto appropriate media as soon as possible. Transport bottles containing medium and a carbon dioxide-enriched atmosphere should be used if definitive specimen processing will be delayed. Transport bottles should be maintained upright during inoculation to preserve the carbon dioxide atmosphere.

Adolescents

Endocervical and vaginal swab specimens are preferred for culture in females at risk for or with clinical suspected gonococcal infection.

Culture of the rectum and pharynx in females can be considered optional except when evaluating for sexual abuse.^{29,177} However, in a recent study, addition of pharyngeal culture allowed detection of an additional 11% to 26% of cases versus cervical culture alone among 14- to 21-year-old females.¹²⁴

In males, sites to be cultured depend on the sexual practices and the anatomic sites exposed. Among MSM, rectal and pharyngeal infections occur with frequencies similar to that of gonococcal urethritis.^{35,161,215,225}

Prepubertal Children

Cultures remain of paramount importance in evaluation of prepubertal children with clinically suspected gonococcal infection or who are being screened for STIs that may have been acquired during potential sexual abuse. Culture is preferred for diagnosis of genital tract and rectal, oropharyngeal, and other extragenital sites of infection in children (see Medicolegal section). Vaginal specimens are adequate for diagnosis in prepubertal girls, for whom obtaining endocervical specimens is unnecessary. Urethral specimens are required in boys. Gram stains are considered inadequate for diagnosis or exclusion of gonococcal infection. Nucleic acid amplification tests (NAATs) can be used for rapid diagnosis on vaginal and urine specimens from girls, but there are insufficient data for their use in boys.³⁴³

FIG. 89.12 Gram stain of gonorrheal exudate showing multiple intracellular diplococci. In male urethral specimens, this is considered diagnostic of gonococcal infection. In children and adolescent females, confirmation by culture or nucleic acid-based tests is needed. (From American Academy of Pediatrics 2012 Red Book Collection.)

Gram-Stained Smears

In symptomatic males, a Gram stain of a urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative diplococci can be considered diagnostic of infection with *N. gonorrhoeae* (Fig. 89.12). Gram stain in this population has greater than 99% specificity and greater than 95% sensitivity.³⁴³ Negative Gram stain results are not sufficient to exclude the diagnosis of gonorrhea. Although nonpathogenic *Neisseria* spp. and *N. meningitidis* are morphologically indistinguishable from gonococci, the former rarely are cell-associated.

Gram stains of endocervical, pharyngeal, and rectal specimens are not recommended because of lower sensitivity in detection of infection at these sites. The specificity of a negative Gram stain appears to be at least 95% for specimens from the endocervix and rectum.^{161,275,343}

Gram stains of eye exudates, joint fluid, and pustular fluid should be performed because the presence of gram-negative diplococci may help guide initial therapeutic interventions pending culture results.

Nonculture Diagnostics

Nonculture diagnostic tests are widely used for rapid diagnosis of gonococcal (and chlamydial) infection. Many offer the advantage of

using urine samples rather than the more invasive swabs and also allow *C. trachomatis* to be evaluated with the same specimen. Numerous gonococcal antigen-detection tests were developed but have been supplanted largely by NAATs. Nucleic acid hybridization tests (NAHTs) also are available. NAHTs are based on a single-stranded DNA probe complementary to gonococcal ribosomal RNA (rRNA). Sensitivities are about 95% (less than culture), with a specificity of 99%.^{147,161,198,247}

NAATs use standard PCR-based assays, transcription-mediated amplification, or strand-displacement assays (SDA). These are more sensitive than culture. False-positive reactions with PCR- or SDA-based NAATs can occur as a result of the carry-over contamination that occurs during processing or because of occasional cross reactions with commensal *Neisseria* spp. that may be present in some clinical specimens. Specificities are generally greater than 98%. False-negative results can occur as a result of target sequence differences (or absence) in some gonococcal clones. NAATs can be used to evaluate first-void urine specimens, which facilitates screening for gonococcal infection in lieu of more invasive genital tract specimens.^{70,301,328,329,338} NAATs can detect the presence of nonviable gonococcal microbes thereby possibly reducing the need for the stringent transport conditions often required for culture. Currently available NAATs are multiplex tests that also can detect *C. trachomatis*.

NAATs are approved by the US Food and Drug Administration (FDA) for use with endocervical, vaginal, and urethral (male only) swab specimens and with urine specimens. They are not FDA approved for rectal, oropharyngeal, or conjunctival specimens but can be used for tests of these sites when clinical laboratories have met CLIA regulatory requirements for off-label procedures.³⁴³

Results of NAATs are adequate for making treatment decisions and public health case identifications. Culture remains the definitive test for medicolegal purposes, although use of NAATs with confirmatory testing with a second NAAT based on an alternative DNA target may be acceptable for forensic use on urine samples from girls but not boys.^{26,290} In addition, because of ever-increasing resistance to the available antimicrobial agents, monitoring of gonococcal susceptibility by culture is necessary at the local level, at the very least in patients who do not respond to apparently adequate therapy.^{338,343}

Medicolegal Issues Related to Diagnostic Tests

N. meningitidis and other members of the *Neisseriaceae* family are morphologically and often biochemically similar to *N. gonorrhoeae* and may be isolated from sites such as the vagina, blood, and nasopharynx.^{98,102,339} Accurate identification of *Neisseria* organisms from any pediatric specimen is essential because misidentification of nongonococcal species as *N. gonorrhoeae* may lead to very serious social consequences for children and their families by precipitating concern regarding sexual abuse. A recent report of two cases of meningitis in young children initially misidentified as having *N. gonorrhoeae* but subsequently confirmed as having *N. meningitidis* illustrates that this may be an ongoing issue.³¹⁰ Nonculture methods consistently identify more clinical specimens as positive than do standard cultures.³²⁹ Determining whether such results indicate greater sensitivity, increased false positivity, or a combination of both has been difficult.

Because of this potential for obtaining false-positive results with NAATs, culture has been considered the medicolegal standard for children who require evaluation for suspected sexual victimization, including prepubertal girls with obvious vaginal discharge. Sequential testing using nonculture tests followed by culture if the former is positive has been proposed as a more sensitive approach than culture alone.²⁴⁶ A recent multicenter study using NAATs on urine specimens and using a second NAAT based on an alternative DNA target or species-specific *N. gonorrhoeae* PCR to confirm positive results found no false-positive results.²⁶ The NAAT-based approach increased the number of confirmed gonococcal infections among 485 girls who were suspected victims of sexual assault from 12, based on culture alone, to 16. This approach is now considered an alternative to culture alone on vaginal and urine specimens in girls. Culture remains preferred for urethral specimens from boys and for extragenital specimens from all children.³⁴³

Proper Collection of Clinical Specimens

Urethral exudate from males may be obtained by passing small swabs or bacteriologic loops 2 to 4 cm into the urethra.¹⁵⁰ Endocervical

specimens from postpubertal females are obtained by speculum examination with swabs inserted 1 to 2 cm into the external os after the cervix has been cleansed of external exudate and vaginal secretions.²⁷¹ The swab should be rotated one full revolution and withdrawn. Self-obtained vaginal swabs also provide adequate specimens for nonculture methods.³⁰² This technique has been studied in adolescents. Vaginal specimens collected with tampons also can be used with nonculture methods.³²⁰

In prepubertal girls, cultures can be obtained from the vaginal introitus by gently swabbing the hymenal opening. Deeper insertion is not necessary. Swabs of exudates emanating from the urethral meatus or vaginal orifice also are sufficient for culture.

In persons with symptomatic anorectal infection, rectal specimens should be obtained by anoscopic means, which increases the sensitivity. In asymptomatic persons, rectal specimens can be procured by blindly inserting a swab 2 to 3 cm into the anal canal and applying lateral pressure to avoid entering any fecal mass. Swabs that are grossly contaminated with fecal matter should be discarded.^{90,342}

The posterior pharynx, tonsillar areas, and faucial pillars should be swabbed to obtain adequate specimens for the diagnosis of pharyngeal infection.¹⁶¹

When urine specimens can be used for nonculture methods, the first 15 to 30 mL of voided urine should be collected.^{208,233} Collection of urine should be delayed at least 1 hour after the most recent void to maximize sensitivity.

ANTIMICROBIAL RESISTANCE AMONG GONOCOCCI

Gonococcal strains have been able to acquire resistance to antibiotics since the first agents were introduced. In 1986, the CDC initiated the Gonococcal Isolate Surveillance Program (GISP) to monitor the antimicrobial sensitivities of *N. gonorrhoeae* in STI clinics in 21 cities in the United States.⁵³ This system consisted of 29 sites in 2010.⁶⁰

Sulfanilamide became available in 1936, but widespread resistance to sulfanilamide occurred by 1944.²⁵⁰ As successive agents have become available, multidrug-resistant strains are being seen with increasing frequency in many parts of the world. Ongoing analysis of gonococcal isolates for antibiotic susceptibility to the available antimicrobial agents remains essential for maintaining effective empirical therapeutic regimens.

In the 1940s, virtually all gonococcal isolates were highly susceptible to penicillin. Despite a gradual increase in the mean minimal inhibitory concentration (MIC) to penicillin from the mid-1950s through the mid-1970s, almost all strains had penicillin MICs of less than 0.5 µg/mL. This low-level resistance is mediated by alterations at a genetic locus called *penA* that result in modification of its product, penicillin-binding protein 2. Two other loci designated *mtr*, which encode an efflux pump that reduces concentrations of multiple antibiotics, and *penB*, which is an allele of *por*, the gene of the porin protein, also mediate low-level resistance to penicillins. *penB* encodes a porin with a mutation that decreases permeability to hydrophilic antibiotics.¹²⁶

In 1976, strains of *N. gonorrhoeae* were discovered that had acquired plasmid-conferring resistance to penicillin through the production of penicillinase (a TEM-1 β-lactamase). These strains were found in many parts of the Far East and in London, and in the former they constituted approximately 30% of the isolates in some cities. The strains caused the expected spectrum of clinical disease, and treatment with penicillin was not effective. Penicillinase-producing gonococci contain one of two closely related 5.3- or 7.2-kb plasmids (Pc^r) that carry a Tn2 transposon system. This plasmid appears to have been acquired from *Haemophilus ducreyi*.^{7,23,47,68,252} In 1983, an outbreak of chromosomally mediated, penicillin-resistant (MICs of 2 to 4 µg/mL), non-penicillinase-producing gonococci was reported from North Carolina.¹¹⁶ Such strains were seen subsequently in other areas of the country.

Resistance to tetracycline antibiotics emerged in the 1980s and subsequently increased. Three chromosomal loci designated *mtr*, *penB*, and *tet* mediate low-level resistance. High-level resistance to tetracycline is conferred by *tetM*, which resides on a 38-kb plasmid (Tc^r) that is a derivative of the 36-kb conjugal plasmid. *tetM* produces a cytoplasmic protein that protects ribosomes from tetracycline. Tc^r gonococci can

transfer this plasmid, as well as Pc^r , efficiently to other gonococcal strains.^{231,311}

Spectinomycin resistance was described first in 1987 in US military personnel in Korea. This agent had been introduced as the drug of choice there in 1981 because of high rates of penicillin resistance. Treatment failures actually began to occur in 1983. Resistance is chromosomally mediated and results in alteration of the ribosomal target site of the drug.^{30,47} The widespread use of spectinomycin was associated with a decline in the rate of penicillin resistance.³⁰ All gonococcal strains tested in the United States since 1994 have been susceptible to streptomycin.⁶²

Ciprofloxacin and other fluoroquinolone antibiotics became widely available for the treatment of gonococcal infection in the 1980s. Low-level resistance to fluoroquinolones is associated with mutations in the DNA gyrase gene *gyrA*, and high-level resistance has been linked to mutations in the topoisomerase gene *parC*.¹⁶⁹ Resistance to these agents has been noted since the early 1990s in areas of Southeast Asia.¹¹⁸ In April 2007, the CDC no longer recommended the use of fluoroquinolones for the treatment of gonococcal infections in the United States⁵⁸ as prevalence of resistances to ciprofloxacin increased to 14.8% among GISP isolates. In 2014, 19.2% of GISP isolates were resistant.⁶²

In 1989, 13% of the *N. gonorrhoeae* isolates evaluated were resistant to penicillin, tetracycline, or both.⁵⁴ In 1999, such strains accounted for 28% of all isolates.⁵⁶ Overall in 2014, 37% of isolates evaluated by GISP were resistant to penicillin, tetracycline, ciprofloxacin, or some combination of these antibiotics.⁶² The distribution of azithromycin MICs among gonococcal isolates has shifted upward in the last decade. The proportion of GISP strains with reduced susceptibility (MICs ≥ 2.0 $\mu\text{g/mL}$) has risen from 0.3% in 2011⁶¹ to 2.5% in 2014.⁶² Rifampin resistance is also high in some areas of the world.²⁴⁰

During the past few years cefixime MICs have crept upward in the United States and other countries, along with reports of treatment failures with the recommended 400 mg oral dose of this agent.^{61,209,325} MICs of 0.5 $\mu\text{g/mL}$ or higher are considered to have decreased susceptibility to cefixime. The mechanism of this reduced susceptibility is chromosomally mediated and multifactorial. Mutations in the *penA* encode alterations in penicillin binding protein (PBP) 2 that confer reduced affinity for penicillins. Mutations in the promoter *mtrR* and *porB1b* (*penB*) result in increased efflux capacity and decreased permeability of the cell membrane, respectively, which decrease concentrations of these agents in the periplasm. High-level resistance can result from a mutation of *ponB* that encodes an altered PBP 1.²⁰⁰

Nationally in the United States in 2011, 1.5% of GISP isolates had cefixime MICs of 0.25 $\mu\text{g/mL}$ or higher, a threshold used by GISP for monitoring emerging resistance to cephalosporins (Fig. 89.13). In the Western United States, 3.2% of isolates had MICs at or above 0.25 $\mu\text{g/mL}$. These observations prompted removal of cefixime from recommended options for empirical treatment of uncomplicated gonococcal infections in the United States in August 2012. In 2014, 0.8% of GISP isolates had MICs at or above 0.25 $\mu\text{g/mL}$.

FIG. 89.13 Percentage of *Neisseria gonorrhoeae* isolates with elevated cefixime minimum inhibitory concentrations (MICs) (≥ 0.25 $\mu\text{g/mL}$), Gonococcal Isolate Surveillance Project (GISP), 2006–14. The rise in MIC since 2006 is the result of alterations in the microbial penicillin-binding proteins. Cefixime susceptibility was not tested by GISP during 2007 and 2008. (From Centers for Disease Control and Prevention: <http://www.cdc.gov/std/stats14/figures/27.htm>. For the most currently available data, see <http://www.cdc.gov/std/gisp/default.htm>.)

Ceftriaxone MICs have increased minimally overall to date, with MICs at or above 0.125 $\mu\text{g/mL}$ fluctuating between 0.1 and 0.4% among GISP isolates in recent years.⁶² A few isolates with MICs of 0.5 to 2 $\mu\text{g/mL}$ have been reported.^{61,62,325}

These ongoing events raise concerns about potential emergence of near “pan-resistant” gonococcal strains.

TREATMENT

Because of ever-changing gonococcal susceptibility patterns and variations in susceptibility in different international regions, practitioners must remain alert for modifications of treatment guidelines for their respective geographic locations. Based on the current patterns of antimicrobial resistance in prevalent *N. gonorrhoeae* strains in the United States, the third-generation cephalosporin ceftriaxone is the only remaining agent routinely recommended as initial therapy in children and adults as of August 2012.⁶¹ Dual therapy with azithromycin also may enhance treatment efficacy for gonococcal infections, especially against pharyngeal gonococcal infections in combination with oral cephalosporins. Azithromycin is thus now preferred over doxycycline for treatment of potential concomitant *C. trachomatis* infection.³⁴³

The recommendations for treatment of childhood gonorrhea in the United States discussed in this section and listed in Tables 89.5 and 89.6 are based primarily on 2015 guidelines from the CDC.³⁴³ CDC guidelines are based on the stringent clinical efficacy criterion of an expected 95% efficacy with lower bound of 95% confidence interval of 90%.²³⁸ Up-to-date information on treatment regimens for gonorrhea and other STIs can be obtained from the CDC website <http://www.cdc.gov/std/treatment>.

Treatment of Infants Born to Mothers With Gonococcal Infection

Infants born to mothers with untreated gonorrhea are at high risk for acquiring infection; consequently, even without overt signs of infection, such infants should be treated with a single injection of ceftriaxone (see Table 89.5). Ceftriaxone should be given cautiously to hyperbilirubinemic infants, especially premature ones. A single dose of cefotaxime 100 mg/kg intravenously or intramuscularly is an acceptable alternative. Topical prophylaxis for neonatal ophthalmia is not adequate therapy for documented infections of the eye or other sites.³⁴³

Treatment of Neonates With Gonococcal Infection

Neonates with suspected gonococcal infection of any site, including GON, should be admitted to the hospital for parenteral antibiotics and any needed supportive care. Many but not all experts recommend that CSF studies be performed even in afebrile, otherwise well-appearing infants whose only clinical manifestation is apparent GON.

The presence of typical gram-negative diplococci in Gram-stained specimens is sufficient justification to begin treatment of GON or gonococcal infection in other sites. The absence of gram-negative diplococci in Gram-stained specimens is not sufficient to abrogate presumptive treatment of GON in a neonate with conjunctival exudate.

Tests for concomitant *C. trachomatis* infection, HIV infection, and congenital syphilis should be performed in infants with gonococcal infection at any site. The mother and her partner(s) should be evaluated for gonococcal infection (and other STIs) and treated according to the recommendations for gonococcal infection in adolescents and adults.

Infants with GON can be treated with a single dose of ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly, not to exceed 125 mg (see Table 89.5). This regimen also may be used for infants with other sites of nondisseminated gonococcal infection, including the rectum, pharynx, vagina, and urethra. A single dose of cefotaxime 100 mg/kg given intravenously or intramuscularly is an alternative treatment of GON. Some experts prefer to continue parenteral therapy with one of these agents until blood cultures (with or without CSF cultures) have been negative for 48 to 72 hours. Infants with GON also should receive eye irrigation with saline solution immediately on recognition and at frequent intervals until the discharge is eliminated. Topical antimicrobial agents alone are inadequate and unnecessary when the recommended systemic antibiotics are given.^{59,120,194}

TABLE 89.6 Recommended Treatment of Gonococcal Infections in Children and Adolescents Beyond the Neonatal Period

	Prepubertal Children <45/kg	Patients Age ≥8 Years, ≥45/kg
Uncomplicated Gonococcal Infections^{a,b}		
Vulvovaginitis, endocervicitis, urethritis, proctitis, or pharyngitis	Ceftriaxone 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg	Ceftriaxone 250 mg IM in a single dose
Conjunctivitis ^c	Ceftriaxone 50 mg/kg (maximum, 1 g) IM in a single dose	Ceftriaxone 1/g IM in a single dose
Disseminated or Complicated Gonococcal Infections^{a,b}		
Septic arthritis, sepsis, or arthritis-dermatitis syndrome ^{d287}	Ceftriaxone 50 mg/kg/day (maximum, 1 g/day) IV or IM once daily for 7 days ^{e,f}	Ceftriaxone, 1/g IV or IM once daily for 7 days ^{e,f}
Meningitis or endocarditis ^{g286}	Ceftriaxone 50 mg/kg/day (maximum, 2 g/day) IV or IM given twice daily; for meningitis, duration is 10–14 days; for endocarditis, duration is at least 28 days	Ceftriaxone 1–2/g IV every 12 to 24 h; for meningitis, duration is 10–14 days; for endocarditis, duration is at least 28 days
Epididymitis		Ceftriaxone, 250/mg IM in a single dose ⁹⁵
Treatment for presumed coinfection with <i>C. trachomatis</i>	Erythromycin base or ethylsuccinate 50 mg/kg/day (maximum 2 g/day) PO in 4 divided doses for 14 days or Azithromycin 20 mg/kg (maximum 1 g) PO in a single dose ⁱ	Azithromycin 1/g PO in a single dose is preferred ²⁹⁰ or Doxycycline ^j 100/mg PO twice daily for 7 days ^h

See text for discussion of alternative treatment options, including those for patients with allergies to the recommended regimens above.
 IM, Intramuscularly; IV, intravenously; PO, orally.

^aTherapy for potential (presumptive) coinfection with *Chlamydia trachomatis* also is recommended. See bottom row of Table.

^bAzithromycin provides potential dual therapy for gonococcal strains with reduced susceptibility to cephalosporins, in addition to its role in treatment of chlamydial infection. Prevalence of tetracycline resistance is high among Gonococcal Isolate Surveillance Project isolates, particularly among those with elevated minimum inhibitory concentrations to cefixime.

^cEyes should be lavaged with saline initially and at regular intervals until secretions no longer continue to accumulate.

^dHospitalization for arthritis-dermatitis syndrome should be considered for children based on clinical severity, including those (1) who are unlikely to receive the prescribed treatment because of personal or parent/guardian failure to adhere to the regimen or (2) whose infection has not responded to prior outpatient therapy.

^eSome experts advise a 10- to 14-day course of therapy for gonococcal sepsis or septic arthritis.

^fFor older children and adolescents, parenteral therapy can be discontinued 24 to 48 h after improvement occurs and the 7-day course completed with an appropriate oral antimicrobial agent, based on antimicrobial susceptibility results.

^gChildren or adolescents with gonococcal meningitis or endocarditis should be hospitalized initially.

^hAdd doxycycline 100 mg PO twice daily for 10 days for coverage of chlamydia; for males at risk for epididymitis due to enteric organisms (e.g., those who practice insertive anal sex), add levofloxacin 500 mg PO once a day for 10 days or ofloxacin 300 mg PO twice a day for 10 days.

ⁱChildren who weigh 45 kg or more but are < 8 years generally should not be prescribed doxycycline for treatment of STIs due to concerns about dental staining.

^jData are limited regarding efficacy of azithromycin for treatment of chlamydia in young children, but the single dose and favorable side-effect profile make this agent a reasonable choice. Data from Workowski KA, Bolan GA. Sexually Transmitted Diseases Treatment Guidelines, 2015. *MMWR Recomm Rep*. 2015;64:1–137; and American Academy of Pediatrics: Gonococcal infections. In: Kimberlin DK, ed. 2015 Red Book: Report of the Committee on Infectious Diseases. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:356–67. For potential updates to these recommendations, see <http://www.cdc.gov/std/gonorrhea/treatment.htm>.

Simultaneous infection with *C. trachomatis* should be considered a potential explanation for neonates who do not respond satisfactorily to the recommended treatment.

Disseminated Gonococcal Infection or Scalp Abscess

The recommended therapy for gonococcal arthritis, scalp abscess, and sepsis is ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly given once per day for 7 days. Cefotaxime is an alternative and is preferred for infants with hyperbilirubinemia. For gonococcal meningitis, treatment should be continued for 10 to 14 days, with consideration of the use of higher daily doses of these agents (see Table 89.5).³⁴³

Treatment of Gonococcal Infections Beyond the Neonatal Period

Treatment recommendations for children and adolescents with uncomplicated and complicated gonococcal infection, including PID, are outlined in Table 89.6. Children who weigh 45 kg or more may be treated with dosage regimens as defined for adults. All treatment regimens include agents active against *C. trachomatis* in addition to *N. gonorrhoeae*. Choice of chlamydial regimen also is impacted by age, where routine use of doxycycline is generally avoided for STI treatment in those younger than 8 years.

The recommended regimens generally have not been studied in populations of prepubertal children with either uncomplicated or complicated gonococcal infection, but these regimens are likely to be highly effective in most cases, as they are for older adolescents and adults. As a general rule, children treated with ceftriaxone do not require follow-up cultures, but if treatment regimens other than ceftriaxone are used, follow-up cultures may be indicated.³⁴³

Uncomplicated Gonococcal Infections

Ceftriaxone is the preferred agent for treatment of uncomplicated gonococcal vulvovaginitis, endocervicitis, urethritis, proctitis, pharyngitis, and conjunctivitis beyond the neonatal period (see Table 89.6). Higher dosage is recommended for conjunctival infection. Oral cefixime is no longer recommended as routine therapy since it does not provide bactericidal concentrations as high or sustained as ceftriaxone. Cefixime still may be considered as an alternative agent for a few more years (MICs are expected to continue to climb over time); use of other previously recommended oral cephalosporins, such as cefpodoxime or cefuroxime, should be avoided.³⁴³

Gonococcal infection of the pharynx is more difficult to eradicate than infection of urogenital and anorectal sites. Ceftriaxone has the most reliable efficacy for this site. Spectinomycin (when available) is unreliable because its efficacy against *N. gonorrhoeae* in the pharynx is only about 50%.³⁴³

Disseminated Gonococcal Infection

Septic arthritis, arthritis-dermatitis, and sepsis caused by *N. gonorrhoeae* are treated with ceftriaxone for 7 days (see Table 89.6). Alternative agents include cefotaxime and ceftizoxime. The recommended durations of ceftriaxone therapy for meningitis and endocarditis are 10 to 14 days and at least 28 days, respectively. These treatment durations have not been systematically studied.³⁴³

Pelvic Inflammatory Disease

PID is presumed to be polymicrobial, including anaerobes, in addition to *N. gonorrhoeae*. Combination antimicrobial regimens are required. Hospitalization is warranted for adolescents who are pregnant; have

TABLE 89.7 Recommended Treatment of Pelvic Inflammatory Disease

Recommended Parenteral Regimens	Recommended Intramuscular Plus Oral Regimens
Option 1^{a,b} Cefotetan 2 g IV every 12 h <i>or</i> Cefoxitin 2 g IV every 6 h <i>plus</i> Doxycycline ^c 100 mg PO or IV every 12 h Option 2^{a,b} Clindamycin 900 mg IV every 8 h <i>plus</i> Gentamicin loading dose IV or IM (2 mg/kg) followed by 1.5 mg/kg every 8 h (single daily dosing of 3 to 5 mg/kg can be substituted)	IM/PO Options One of Ceftriaxone 250 mg IM in a single dose <i>or</i> Cefoxitin 2 g IM in a single dose with Probenecid, 1 g PO concurrently as a single dose <i>or</i> Another parenteral third-generation cephalosporin (e.g., cefotaxime, ceftizoxime) <i>plus</i> Doxycycline 100 mg PO twice a day for 14 days <i>with or without^d</i> Metronidazole 500 mg PO twice a day for 14 days

^aAmpicillin-sulbactam 3 g IV every 6 h plus doxycycline 100 mg orally or IV every 12 h is an alternative option for initial parenteral therapy that provides needed broad-spectrum coverage with a modicum of clinical trial data demonstrating efficacy.

^bAdolescents with PID usually can be transitioned from the parenteral regimen to oral therapy for completion of the course within 24 to 48 h. Those with tubo-ovarian abscess should be observed for at least 24 h in an inpatient setting.

^cDoxycycline should be administered PO when possible due to pain associated with its IV infusion.

^dNone of the recommended parenteral third-generation cephalosporins provides adequate anaerobic coverage. Metronidazole should be added unless or until it is known that extended anaerobic coverage is not needed for a particular episode of acute PID.

Data from Workowski KA, Bolan GA. Sexually Transmitted Diseases Treatment Guidelines, 2015. *MMWR Recomm Rep*. 2015;64:1–137. For potential updates to these recommendations, see <http://www.cdc.gov/std/gonorrhea/treatment.htm>.

potential surgical emergencies other than PID, including tubo-ovarian abscess; have not responded to an oral regimen already prescribed for the episode; are unable to follow or tolerate an oral regimen; or have severe illness, nausea and vomiting, or high fever.

Two parenteral regimens are recommended for those requiring hospitalization (Table 89.7 for dosages): (1) *either* cefotetan *or* cefoxitin intravenously combined with doxycycline orally or intravenously; or (2) clindamycin intravenously plus gentamicin, using a loading dose intravenously or intramuscularly followed by maintenance doses. Single daily dosing of gentamicin also can be used. Parenteral therapy can be discontinued 24 to 48 hours after clinical improvement. Oral doxycycline or clindamycin should then be continued to complete a total of 14 days of therapy. Clindamycin is preferred for course completion when tubo-ovarian abscess is present to provide more effective anaerobic coverage.³⁴³

Outpatient regimens recommended for adolescents who are not severely ill, as discussed earlier, and appear able to tolerate oral agents also are listed in Table 89.7. These include a cephalosporin, generally single intramuscular doses of ceftriaxone or cefoxitin (with addition of an oral dose of probenecid with the latter), in combination with 14-day oral courses of doxycycline plus metronidazole. Metronidazole provides anaerobic coverage and treatment for often associated bacterial vaginosis. Other parenteral third-generation cephalosporins (e.g., cefotaxime or ceftizoxime) may be substituted for ceftriaxone or cefoxitin in these regimens. Other regimens may become recommended over time when supported by data from more clinical trials.³⁴³

Quinolone-based oral regimens are no longer recommended for routine use because of prevalence of gonococcal resistance to these agents. However, if a cephalosporin-based regimen is not feasible, a fluoroquinolone plus metronidazole may be used (both for 14 days) if a culture for *N. gonorrhoeae* showing susceptibility to quinolones is documented. Levofloxacin 500 mg, moxifloxacin 400 mg, or ofloxacin 400 mg, each orally once daily, are the agents of choice.³⁴³

Substantial clinical improvement is expected within 72 hours after initiation of therapy. Those failing oral regimens should be hospitalized and switched to parenteral regimens. Diagnostic testing (i.e., imaging or laparoscopy) should be considered in such cases.

Severe Allergies to Cephalosporins

Selection of alternative antibiotic therapies for persons with a history of a reaction to a cephalosporin must be guided by the severity of the reaction and the availability of suitable alternative regimens. Desensitization can be considered but may be impractical. There are no data for specific alternative regimens for treatment of gonococcal infections in

children with apparent severe IgE-mediated penicillin or cephalosporin allergy or other adverse reactions such as Stevens-Johnson syndrome. In adults, currently suggested options for treatment of uncomplicated infection in such persons are *either* a single dose of oral gemifloxacin (320 mg) *or* a single intramuscular dose of gentamicin (240 mg) *plus* a single oral dose azithromycin (2 g). Spectinomycin can be considered for urogenital or anorectal infection is available.³⁴³ Agents such as fluoroquinolones or doxycycline may be used if the isolate is known to be susceptible.

Infection With Human Immunodeficiency Virus

Children and adolescents infected with HIV who acquire a gonococcal infection should receive the same treatment as persons without HIV infection.

Concurrent Syphilis Infection

A single dose of ceftriaxone is not adequate for treating syphilis. Longer courses of therapy are required with penicillin-based regimens (see Chapter 144).

Pregnancy

Quinolone and tetracycline agents should be avoided during pregnancy. Those unable to take one of the recommended cephalosporin regimens can be treated with the 2-g dosage of azithromycin. Spectinomycin would be appropriate if available.

Presumptive Treatment of Chlamydia Trachomatis Coinfection

Persons with gonococcal infection, including children, are at high risk for acquiring concurrent chlamydial infection.²⁴¹ Coinfection may occur in more than 50% of teens with gonorrhea.¹⁷⁹ In adolescents, treatment of gonococcal cervicitis with drug regimens that are effective against gonococci but not *Chlamydia* has been associated with a high incidence of residual salpingitis in females and urethritis in males because of persisting *C. trachomatis*.^{249,261,264,291}

Therefore treatment recommendations for gonococcal infections beyond the neonatal period include agents active against both organisms (see Table 89.7). Neonates with gonococcal infections also should be evaluated for *C. trachomatis* coinfection as dual vertical transmission can occur. Penicillin, amoxicillin, ceftriaxone, or spectinomycin alone will fail to eradicate *C. trachomatis*. Trimethoprim-sulfamethoxazole, tetracycline, doxycycline, azithromycin, and erythromycin are effective in vitro and in many clinical forms of chlamydial disease.

Follow-Up

The recommended ceftriaxone regimens have such high cure rates that routine testing for cure is not recommended. As with adults, children or adolescents who receive treatment regimens other than ceftriaxone should have test of cure by culture or NAAT 14 days after treatment.³⁴³ If a NAAT is performed and is positive, culture should be obtained prior to initiation of a second treatment regimen to provide antimicrobial susceptibility data and assess for the possibility of infection by a different microbe. Reinfection is generally more likely than treatment failure, though ongoing surveillance for the latter due to antimicrobial resistance is a critical public health function.

Adolescents treated for gonorrhea and remaining sexually active, regardless of whether they believe their partner(s) have been treated, should be retested at 3 months for potential reinfection or whenever they next present for health care. Partners who have had sexual contact within the previous 60 days with an adolescent diagnosed with gonococcal infection should be evaluated and treated.³⁴³

GONOCOCCAL INFECTION AND SEXUAL ABUSE OF CHILDREN

When gonococcal infection or any other STI is identified in a prepubertal child or in adolescents who are not sexually active within their peer groups, sexual abuse must be considered to have occurred unless proved otherwise. Nonsexual transmission never should be assumed without extensive investigation of the social setting of an infected child and even then rarely.^{236,343} Isolation of *N. gonorrhoeae* in cultures from children should be reported to local public health authorities and also to child protective services to ensure that the child is not exposed to further abuse. Sexual abuse has been reported in approximately 10% of all self-reporting populations of girls during childhood in numerous studies, and rates in boys are about 3%.^{13,278} Approximately 1% of children appear to experience serious forms of sexual abuse yearly.⁵

STIs occur in 3% to 20% of sexually abused children, with gonococcal infections found in about 3% to 15%.^{93,127,166,168,167,228,270,296,332,337} The absence of STDs does not rule out sexual abuse when other findings suggest that it has occurred. The prevalence and clinical manifestations of gonococcal infection in sexually abused children are determined by the prevalence of infection in the adults who constitute the population with whom the child resides, the age of the child, and the type and frequency of sexual contact.²⁴⁶ As a result of improved control of gonorrhea in the 1980s, fewer pediatric cases have been recognized in the United States in recent years. Nonetheless girls who are exposed to an infected male appear to have a high rate of acquired disease. In an outbreak in an orphanage, 53 of 95 abused girls were found to have contracted infection.²

Among prepubertal girls who develop vaginal discharge after being sexually abused, gonococcal infection is the etiology in 9% to 24%.^{127,166,294,296} Although most cases of gonorrhea in prepubertal children are associated with vaginal discharge, infection without evident discharge can occur.¹²⁷ The oropharynx also is a common site of gonococcal infection associated with sexual abuse of children and may be the only site of infection in children forced to perform orogenital sexual acts with an infected abuser. Pharyngeal infection may be asymptomatic. When STIs result from sexual abuse, these may be the only evidence that such abuse has occurred.¹⁶⁵

Children with suspected gonococcal infection (or suspected to have suffered sexual abuse) should undergo a thorough physical examination by someone familiar with the medicolegal and clinical aspects of sexually abused children. Genital, rectal, and pharyngeal cultures should be obtained. Vaginal cultures are satisfactory in prepubertal girls. Endocervical cultures should be obtained only after puberty. Blood culture should be performed if disseminated disease is a consideration. Other sites (e.g., conjunctivae and joint fluid) should be cultured if clinically indicated. Cultures should be handled in a manner that will ensure legal acceptance if needed. When gonococcal isolates are available from both the sexual abuse victim and the alleged assailant, comparison of DNA fingerprints by methods such as PFGE may provide supporting evidence.²⁸⁶

NAATs occasionally may be used as an alternative to culture for forensic purposes for vaginal and urine specimens in girls, but not for these specimens from boys or extragenital specimens in boys or girls.^{246,290}

Children who are being evaluated for sexual abuse should be evaluated for other STIs, including chlamydial disease, syphilis, hepatitis B, and HIV infection. Girls also should be evaluated for evidence of *Trichomonas vaginalis* and bacterial vaginosis by wet mount of vaginal swabs.^{59,143,280} As a general rule, children undergoing evaluation for STIs should not have initiation of treatment until all appropriate diagnostic specimens have been obtained.³⁴³

Repeat physical examination and specimen collection may be warranted 2 weeks after initial evaluation, especially when the suspected abuse event was very recent. Repeat examination and serologic testing for syphilis, hepatitis B, and HIV should be provided at 6 weeks and 3 months after the last suspected sexual exposure.³⁴³ A single evaluation may be sufficient if suspected abuse occurred over an extended period and a substantial amount of time has elapsed since occurrence of the last suspected episode. This is determined on a case-by-case basis.⁵⁹

PREVENTION AND CONTROL OF GONOCOCCAL INFECTIONS

The US Preventive Services Task Force and the CDC both recommend that all sexually active women aged 24 years or younger at high risk of gonorrhea and chlamydia infection be screened with a NAAT that can detect these microbes.^{321,343} Risk factors to be assessed include new or multiple sex partners, inconsistent condom use in persons not in a monogamous relationship, prior or concurrent STIs, and exchanging sex for money.³²¹ The CDC also recommends such testing annually for males who have sex with other males.³⁴³

All gonococcal infections must be reported to public health officials. Effort should be made to evaluate, counsel, and treat all sexual partners who were exposed to the index case within 60 days before the onset of symptoms or diagnosis in the index case. If a patient's last sexual intercourse occurred more than 60 days before the onset of symptoms, the most recent sexual partner of the patient should be evaluated and treated. Patients should be instructed to avoid engaging in sexual activity until therapy is completed and any symptoms have resolved. Cases in prepubertal children must be investigated to identify the source of infection (and potential perpetrator of abuse).³⁴³

Condoms provide a high degree of protection against the acquisition and transmission of genital gonococcal infection.^{176,326} Other barrier contraceptive measures and topical spermicidal and bactericidal agents likewise can reduce the likelihood of acquiring gonococcal (and chlamydial) infection.^{14,52,212,314} Postexposure prophylactic antibiotics also reduce the risk for infection developing but are unlikely to be cost-effective.¹⁵¹

When patients, including infants with ophthalmia neonatorum, with gonococcal infection are hospitalized, standard precautions are recommended.

Prevention of Neonatal Infection

Pregnant adolescents are at higher risk for contracting gonococcal infection than are older women. Pregnant women should have an endocervical culture for *N. gonorrhoeae* as part of their initial prenatal care visit. A second culture late in the third trimester should be performed for those at high risk for exposure during pregnancy.

Infants born to mothers known to have active gonococcal infection are at risk for acquiring local and disseminated infection from colonization during birth. Such infants should be treated as listed in Table 89.5. Standard preventive measures for GON were described earlier.

Vaccine Development

Research into the development of vaccines for gonococcal infection is ongoing. Although natural infection induces antibody responses directed primarily against pili, Opa, porin protein, and LOS, these antibodies do not protect against reinfection even with the same strain. Serologic correlates of immunity remain elusive, making vaccine development more difficult. A killed whole-cell vaccine studied in the 1970s induced antibody responses and was well tolerated but not protective. A purified pilin vaccine was studied in high-risk military personnel and also was not protective.³⁴⁵

Molecular analysis of gonococcal transferrin binding proteins may have potential as vaccine antigens because of their exposure on the microbial surface. These proteins are expressed in all strains, have highly conserved gene sequences, and lack antigenic and phase variation. Natural infection, however, generates little systemic or local antibody response to transferrin binding proteins.^{50,257} Recent structure–function analysis of the transferrin receptor system may be an important step toward identifying an approach to immunogenic epitopes or novel therapeutic small-molecule inhibitors of this gonococcal system.⁵⁰

As with meningococcal serogroup B strains, use of combinations of recombinant antigens, potentially delivered in different formats, may be necessary. The continued emergence of antimicrobial resistance in *N. gonorrhoeae* makes vaccine development increasingly urgent.

SUBSECTION III Gram-Positive Bacilli

Diphtheria

90

Barbara W. Stechenberg

Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae* or, less commonly, *C. ulcerans*. *C. pseudotuberculosis*, which primarily causes infections in sheep and goats, is not discussed here because it only rarely causes a diphtheria-like disease in humans. Infection by toxigenic strains of *C. diphtheriae* causes disease that is mediated by the production of an extracellular protein. Nontoxigenic strains also can cause disease, but it is usually less severe.

Before the discovery of antitoxin at the turn of the 20th century, the “strangling angel of children,” as diphtheria once was called, was a significant cause of mortality in children and adults.¹⁰⁸ Apparent reference to diphtheria can be traced to the 5th century BC in the works of Hippocrates, *Epidemics III*, case 7.⁷⁹ In 1821, it was recognized as a specific entity by Brettoneau, who suggested that the disease was caused by a germ and that it could be transmitted from person to person. Brettoneau coined the origin of the modern term *diphtheria* from the Greek root *diphtheria*, which means “skin” or “hide.”⁵⁰ In 1883 the causative agent was identified by Klebs in stained smears from diphtheritic membranes; in 1884, Löffler grew the organism on artificial media and showed that in guinea pigs it caused a fatal infection closely resembling human disease.

The toxin was purified in 1889 by Roux and Yersin, who found that toxin alone could cause the disease. Shortly thereafter, Behring and Kitasato discovered antitoxins when they immunized animals with toxins rather than bacteria. The use of antitoxin to treat children with diphtheria at the turn of the 20th century resulted in one of the largest decreases

in mortality rates by a therapeutic intervention. In Germany alone, an estimated 45,000 lives were saved each year.⁶²

ETIOLOGY

Corynebacteria (Klebs-Löffler bacilli) are irregularly staining, gram-positive, nonmotile, nonsporulating, pleomorphic bacilli.⁵⁴ The club-shaped appearance of the bacillus is not a true morphologic feature, but results from attempting to grow the bacillus on media that are nutritionally inadequate (Löffler media). The organism can be recovered most readily on media containing selective inhibitors that retard the growth of other microorganisms; a sheep blood agar-based medium containing fosfomycin (for selectivity) and Tindale medium (tellurite medium with cystine) are ideal.^{43,44} *C. diphtheriae* and *C. ulcerans* grow on supplement-free blood agar, chocolate agar, and other standard media.⁴³

Colonies of *C. diphtheriae* (with the exception of the lipophilic, gray *C. intermedius*) and *C. ulcerans* appear grayish white on Löffler medium. On tellurite medium, three diphtheria colony types can be distinguished: *mitis*, *gravis*, and *intermedius*. *Mitis* colonies are smooth, black, and convex; they do not ferment starch or glycogen and are hemolytic. *Gravis* colonies are gray, radially striate, and semirough; they ferment starch and glycogen and usually are not hemolytic. *Intermedius* colonies are small and smooth and have a black center; they do not ferment starch or glycogen and are not hemolytic. *C. ulcerans* colonies resemble

gravis on Tindale medium but differ in that they are hemolytic. Similar to *gravis*, they ferment starch and glycogen. All diphtheria biotypes and *C. ulcerans* are characterized by cystinase activity and absence of pyrazinamidase activity. *C. ulcerans* may be distinguished from *C. diphtheriae* by its urease activity and ability to liquefy gelatin. Biotype *belfanti*, which does not occur in a toxigenic form, may be distinguished from the three potentially toxigenic diphtheria biotypes by its inability to reduce nitrate on Tindale medium and from *C. ulcerans* by its lack of production of urease.⁴³ Ribotyping and pulsed-field gel electrophoresis, both of which involve restriction digestion of genomic bacterial DNA, followed by gel electrophoresis and Southern blotting, permit more specific typing within each diphtheria biotype and aid in the epidemiologic study of outbreaks.^{41,95}

C. diphtheriae biotypes *intermedius*, *gravis*, and *mitis* and *C. ulcerans* all have been observed in a toxigenic form. *Intermedius* was the biotype isolated most commonly in the United States between 1971 and 1981. Of the strains isolated, *intermedius* was found to be toxigenic more often than *mitis* or *gravis*.³⁶ In the United Kingdom between 1993 and 1998, and similarly in other parts of Europe, the biovar *gravis* has represented most nontoxigenic isolates, followed by *mitis* and *belfanti*.⁴⁵ Of the four nontoxigenic isolates obtained during a surveillance study of a U.S. Northern Plains Native American Community in 1996, two were of biotype *mitis* and two were *gravis*.⁵⁹ According to a UK diphtheria reference laboratory, between 1993 and 1998, the toxigenic isolates originating from Asia, Africa, and the Middle East were reported to be of the biotype *mitis* or *gravis*, with the exception of one *intermedius* isolate.⁴⁴ Golaz and associates⁵⁹ reported similar findings when they surveyed the different biotypes in South Dakota. A significant overall increase in the proportion of nontoxigenic isolates has been observed in Europe and Australia in recent years.⁵⁸ The reason for this increase is unclear, but one hypothesis is that increased immunity to toxigenic strains secondary to immunization has altered this epidemiology.

The complete genome sequence of *C. diphtheriae* biotype *gravis* has been elucidated.³³ The genome is approximately 2.48 Mb with a G+C content of 53% and has approximately 2320 predicted coding sequences. Metabolic analysis of the genome has revealed that *C. diphtheriae* has a complete set of enzymes for glycolysis, gluconeogenesis, pentose-phosphate pathways, anaerobic and aerobic respiration, amino acid biosynthesis, and purine nucleotide biosynthetic pathway. Most of the enzymes for the tricarboxylic acid cycle are present, with the exception of an enzyme succinyl coenzyme A (CoA) synthetase that catalyzes the conversion of succinate to succinyl CoA. An alternative enzyme present in *C. diphtheriae* may fulfill this conversion, however. The pyrimidine pathway in *C. diphtheriae* lacks an enzyme that interferes with the production of cytidine; the pathway to the biosynthesis of thymidine is complete. The genome has revealed 13 regions that are unique to *C. diphtheriae* and may serve as pathogenicity islands.³³

No functional or significant differences have been detected in the exotoxins elaborated by the three strains of *C. diphtheriae* or by *C. ulcerans*. Only strains that are lysogenic for β -prophage or a closely related phage carrying the gene for toxin production produce diphtheria toxin. One or more *tox* gene sequences may exist in the bacterial genome, and the most highly toxigenic strains contain three or more copies.⁸² Phage multiplication is not a prerequisite for the production of toxin. The capacity to synthesize toxin depends on genetic and nutritional factors. Toxin-producing cells apparently are cells in which spontaneous induction of the prophage to the phage occurs.⁵³ The most important factor controlling the yield of toxin is the concentration of inorganic iron in the culture medium.³⁹ Growth of *C. diphtheriae* in iron-deficient media prolongs the duration of induction lysis and is associated with a high yield of toxin. High concentrations of iron inhibit the production of toxin. Production of toxin also can be increased by the use of ultraviolet radiation. Conversion to a toxigenic strain occurs in nature, as has been shown by restriction enzyme studies of carriers of toxigenic and nontoxigenic strains in Manchester, England.

The ability of a strain of *C. diphtheriae* to elaborate diphtheria toxin can be shown by using several methods. In vivo studies involving necrosis of tissue in guinea pigs has been replaced by the widely used Elek⁴⁶ or modified Elek test.⁴⁹ Enzyme immunoassay⁴⁸ and polymerase chain reaction (PCR)⁹⁴ have been used to detect toxigenicity.

Diphtheria toxin is lethal to humans in an amount of approximately 130 $\mu\text{g/kg}$ body weight. Cytoplasmic internalization of 1 molecule of toxin has been shown to cause cell death.¹¹ Toxigenic and nontoxigenic strains of *C. diphtheriae* can cause disease, but only strains that produce toxin cause disease with symptoms of myocarditis and neuritis.

EPIDEMIOLOGY

Asymptomatic human carriers serve as the reservoir for *C. diphtheriae*. Infection by *C. diphtheriae* is acquired by contact with either a carrier or an individual with active disease. The bacteria may be transmitted via droplets during coughing, sneezing, or talking. Rarely transmission of *C. diphtheriae* occurs from skin lesions or fomites. Some reports suggest that skin carriers of *C. diphtheriae* are more infectious than nose or throat carriers and that skin carriers may serve as potential reservoirs for the initiation of epidemic spread.^{12,68} In areas in which skin infections are endemic, levels of natural immunization may be high.²⁰ This phenomenon is illustrated particularly well in a survey of tetanus and diphtheria immunity in a rural Kenyan community, where age was not found to be predictive of immunity, and no correlation was found between levels of antibody for tetanus and diphtheria.⁷⁷

Person-to-person transmission of *C. ulcerans* is not known to occur, although *C. ulcerans* was isolated from the siblings of two patients reported in the United Kingdom between 1995 and 1997.¹⁷ Cases of respiratory diphtheria caused by *C. diphtheriae* and *C. ulcerans* have been documented in association with contaminated unpasteurized milk taken from cows with infected teats.^{18,60,104} *C. diphtheriae* has been isolated from horses, dogs, and other domestic animals. *C. ulcerans* has been reported to infect ground squirrels in the United States, but transmission to humans has not been reported.^{67,93} *C. ulcerans* is a commensal in animals and has been isolated in a wide range of wild and domestic animals.¹⁰⁵

According to World Health Organization (WHO) reports, diphtheria is distributed worldwide and remains endemic in many developing areas of the world, including Asia, Africa, South America, and the Mediterranean regions.¹⁹ Worldwide, diphtheria epidemics have occurred in a cyclic manner since the 16th century. In 2014, 7321 cases of diphtheria were reported to the WHO, although many others were likely unreported.

In the United States, the incidence and mortality rates from diphtheria in the 1920s were 140 to 150 cases/100,000, with 13,000 to 15,000 deaths each year. The number of cases gradually declined to 15 cases/100,000 population in 1945 with the extensive use of diphtheria toxoid vaccine. From 1970 through 1979, the average number of cases of diphtheria reported annually in the United States was 196.⁸ From 1980 to 2004, only 57 cases of diphtheria were reported in the United States. Approximately 75% of the cases were in patients older than 15 years who were unimmunized or inadequately immunized.⁸ Only two cases of diphtheria have been reported in the United States between 2004 and 2015. Maintenance of immunity in adults requires a booster vaccination every 10 years. The Centers for Disease Control and Prevention (CDC) estimated in the mid-1990s that fewer than 50% of adults in the United States had received their 10-year boosters and that 40% to 50% of adults were susceptible to diphtheria.^{52,96} In addition, the toxoid vaccine does not provide protection against nontoxigenic strains.

The incidence peaks during the cooler autumn, winter, and spring months. Several epidemics, primarily in the southern United States, have occurred in late summer and fall and corresponded to a high prevalence of *C. diphtheriae* skin infections. Between the years 1971 and 1981, the incidence of diphtheria was highest in the western United States. A 100-fold greater incidence of diphtheria occurs in Native Americans than in the general population.³⁶ This difference may be attributable to socioeconomic factors more than to race. In 1996, a surveillance study was conducted in a Northern Plains Native American community after *C. diphtheriae* was isolated from the skin of a resident of the community. The woman was a chronic alcoholic admitted to the hospital for detoxification and treatment of severe necrotizing leg ulcers, from which a toxigenic *mitis* biotype was isolated. In the following 4 months, 11 positive cultures were obtained from the community, including four positive throat swabs from asymptomatic household contacts of the index cases. Ribotyping indicated that the isolates were

related closely to each other genetically and to strains obtained from past cases from the same area; they were different from organisms obtained from other parts of the United States and from the former Soviet Union, where an ongoing epidemic was occurring at the time.^{25,59} A similar study was conducted in a Koorie (Aborigine) community in Victoria, Australia, in 1994, after three cases of nontoxigenic *C. diphtheriae* endocarditis were diagnosed in the community. After screening 359 asymptomatic (with the exception of four people who had chronic skin ulcers swabbed) contacts of the index cases, 12 produced positive cultures for nontoxigenic *C. diphtheriae*. Of them, five were of the same biovar *gravis* clone as the three index cases.⁶⁹ Evidence that diphtheria is diagnosed more frequently in chronic alcoholics and the indigent than in the general population is significant. In a 1993 to 1994 outbreak in St. Petersburg, Russia, 69% of a total of 42 deaths occurred in individuals classified as chronic alcoholics.⁹⁸ Between 1972 and 1982, three outbreaks occurred in the indigent alcoholic population living in Seattle's Skid Road.⁶⁶ Cutaneous infections accounted for 86% of the 1100 total cases. The first outbreak was caused by a single toxigenic *intermedius* biotype clone, whereas the other two involved nontoxigenic *mitis* and *gravis* strains. The incidence was highest in winter and spring.

A major epidemic began in 1990 in the new independent states of the former Soviet Union and spread throughout the area. Between 1990 and 1997, approximately 150,000 cases of diphtheria were reported, with approximately 4000 fatalities.^{65,95} The epidemic was attributed to decreasing immunization rates and immunity in adults and children and to movement of large numbers of people during the collapse of the former Soviet Union.^{23,106} Apparently multiple foci of infection existed across the continent. Most of the epidemic isolates from Ukraine and Russia were biotype *gravis*, but further molecular characterization of the *tox* genes from these areas revealed distinct epidemic strains in each location.⁷⁰ A mass immunization program was initiated in Russia in 1993, with a resultant 10% decrease in the number of new cases reported between 1994 and 1995 (vs. two- to threefold increases in the number of cases each year for the preceding 3 years).⁵⁷ The WHO also held training workshops and assembled laboratory kits to assist in establishing the proper diagnosis of diphtheria. Because cases also began to appear in Europe with increasing frequency during this period, the European Working Group on Diphtheria (ELWGD) and reference laboratories were assembled to assist in an effort to increase routine screening for diphtheria. The ELWGD since has expanded and currently includes 20 participating countries, including representatives in Western and Eastern Europe, the United States, Australia, and Southeast Asia.⁴⁵ Surveillance from Europe from 2000 to 2009 has documented a decrease in incidence of more than 95% across the region, with the Russian Federation and Latvia accounting for 83% of the cases. In Western Europe, toxigenic *C. ulcerans* has increasingly been identified, often in association with contact with companion animals.¹⁰⁷ More recently there have been documented cases, particularly of cutaneous diphtheria, in refugees and asylum seekers in Europe.

PATHOGENESIS AND PATHOLOGY

Diphtheria is initiated by entry of *C. diphtheriae* into the nose or mouth, where the bacilli remain localized on the mucosal surfaces of the upper respiratory tract. Occasionally the ocular or genital mucous membranes serve as the site of localization. The bacilli are unable to invade intact skin but may infect preexisting skin lesions. After a 2- to 4-day period of incubation, lysogenized strains may elaborate toxin.

Diphtheria toxin is secreted as a single polypeptide of 535 amino acids with a molecular weight of 58,342 Da.⁷⁰ The toxin is composed of two subunits: a large B subunit that is involved in receptor binding and an A subunit that is the enzymatically active portion of the toxin. The toxin initially is absorbed onto the target cell membrane by binding a receptor on the cell surface and then undergoes receptor-mediated endocytosis. When it is in the endolysosomal complex, it undergoes a conformational change with subsequent release of the A subunit into the cytoplasm. The A subunit transfers an adenosine diphosphate (ADP)-ribosyl group from nicotinamide adenine dinucleotide (NAD) to elongation factor 2. This ADP-ribosylation inactivates elongation factor 2 and inhibits protein synthesis in the cell. Cholera and pertussis

toxins also mediate target protein ribosylation by this mechanism. In addition to the inhibition of cellular protein synthesis, an independent mechanism of cytolysis has been described. In the presence of calcium and magnesium, diphtheria toxin has a nuclease-like activity that causes DNA fragmentation that results in cytolysis.^{34,35,70,78}

Marked toxin-mediated tissue necrosis occurs in the vicinity of *C. diphtheriae* colonization and induces a robust local inflammatory response. The inflammatory response coupled with the necrotic tissue produces a patchy exudate that initially can be removed. As the infection progresses, the increased production of toxin causes a centrifugal widening of the area of infection, and eventually a fibrinous exudate develops. A tough adherent membrane results from coagulation of the exudate. The color of the pseudomembrane initially is white but, over the course of time, becomes dirty gray. Late in the course of the infection, green or black spots appear on the membrane, representing areas of necrosis. Histologic analysis of the pseudomembrane differs based on the site of formation and maturation of the membrane. Analysis of the pharyngeal pseudomembrane shows fibrin; inflammatory cells, primarily composed of neutrophils, red blood cells, and colonies of organisms; and superficial epithelial cells.

With severe infections, significant vascular congestion, interstitial edema, fibrin exudate, and intense neutrophilic infiltration develop.⁶⁴ Profuse bleeding can occur when the membrane is torn off. The edematous tissue and the diphtheritic membrane may encroach on the airway. The membrane sloughs spontaneously during the recovery period, although sloughing can occur during the acute phase of the illness, leading to aspiration. Occasionally secondary bacterial infection (classically caused by *Streptococcus pyogenes*) develops. Respiratory embarrassment or suffocation may occur, with involvement of the larynx or tracheobronchial tree. Bronchopneumonia may develop if the exudate enters the small airways and alveoli. Infection of these sites is an uncommon occurrence, however. Infections of the esophagus and stomach, with pseudomembranous lesions indistinguishable from lesions found in the respiratory tract, have been reported.⁷²

Toxin produced at the site of infection is distributed throughout the body by the bloodstream and the lymphatics. This distribution occurs most readily when the pharynx and tonsils are covered by a diphtheritic membrane. Any organ or tissue can be damaged as a result of diphtheria toxin, but lesions of the heart, nervous system, and kidneys are particularly prominent. Clinical manifestations appear after a variable latent period of 10 to 14 days for myocarditis and 3 to 7 weeks for manifestations in the nervous system, such as peripheral neuritis. In a study of 102 patients who died of diphtheria caused by *C. diphtheriae*, the hearts appeared dilated, flabby, and pale, with a characteristic "streaky" appearance in the myocardium. The most prominent pathologic findings are necrosis and hyaline degeneration of the myocardium. The myocardium also appears edematous and is infiltrated with mononuclear cells with eosinophilic cytoplasm. In a significant proportion of cases, fatty accumulation in muscle fibers and the conducting system may be observed.⁸⁹ Burch and associates²¹ showed mitochondrial damage with depletion of glycogen and accumulation of lipid droplets in the damaged myofibrils. Toxin may be observed within the myocardial cells with fluorescent antibody staining.⁶⁴ If the patient survives, muscle regeneration and interstitial fibrosis can be seen.

Peripheral neuropathy occurs secondary to *C. diphtheriae* infections. Histologic studies have shown that affected nerves have significant degeneration of myelin sheaths and axons. Toxic neuritis with fatty degeneration of paranodal myelin can be noted early in the disease course; segmental demyelination occurs later.⁹ Axonal damage is secondary to the application of external pressure from the swollen Schwann cell cytoplasm and myelin.⁸¹

C. diphtheriae infections also can lead to necrosis and hyaline degeneration of the liver, which can lead to hypoglycemia. Adrenal hemorrhage and acute tubular necrosis of the kidney have been known to occur secondary to *C. diphtheriae* infections.⁶⁴

CLINICAL MANIFESTATIONS

The signs and symptoms of diphtheria depend on the site of infection, the immunization status of the host, and whether toxin has been

distributed to the systemic circulation. The incubation period is 1 to 6 days (range, 1 to 10 days). Diphtheria can be classified clinically on the basis of the anatomic location of the initial infection and the diphtheritic membrane (nasal, pharyngeal/tonsillar, laryngeal or laryngotracheal, skin, and others) involved. More than one anatomic site may be involved simultaneously.

Nasal diphtheria initially resembles a common cold and is characterized by mild rhinorrhea and a paucity of systemic symptoms. Gradually the nasal discharge becomes serosanguineous and then mucopurulent. A foul odor may be noticed, and careful inspection reveals a white membrane on the nasal septum. In severe cases, the infection may excoriate the nares and upper lip. Nasal diphtheria is a mild form of the disease because absorption of toxin usually is slow from this site. Frequently delays in establishing an accurate diagnosis of nasal diphtheria occur because of the lack of systemic symptoms. The nasal form of the disease occurs most often in infants.

Pharyngeal and tonsillar diphtheria begin insidiously with anorexia, malaise, low-grade fever, and pharyngitis. Within 1 or 2 days, a membrane appears. The extent of membrane formation correlates with the immune status of the host; in some partially immune individuals, a membrane may not develop. The white or gray adherent membrane may cover the tonsils and pharyngeal walls and extend on to the uvula and soft palate or down on to the larynx and trachea. Attempts to remove the membrane are followed by bleeding. Cervical lymphadenitis varies. In some cases, it is associated with edema of the soft tissues of the neck and may be so severe that it gives the appearance of a "bull neck." In a 1970 epidemic, "erasure" edema of the neck was noted in patients with pharyngeal diphtheria.⁸⁵ Patients with erasure edema did not have a classic bull neck appearance, but the edema was characterized by obliteration of the sternocleidomastoid muscle border, the mandible, and the median border of the clavicle. The edema was brawny, pitting, warm to the touch, and tender to palpation. Erasure edema was noted in 29% of immunized patients and 30% of nonimmunized or inadequately immunized patients. It occurred most commonly in children older than 6 years and generally was associated with infection by the *gravis* or *intermedius* strain of *C. diphtheriae*.

The course of pharyngeal diphtheria depends on the degree of elaboration of the toxin and the extent of the membrane. In severe cases, respiratory and circulatory collapse may occur. The pulse rate is increased disproportionately to body temperature, which generally remains normal or slightly elevated. The palate may be paralyzed. This paralysis may be unilateral or bilateral and associated with difficulty swallowing and nasal regurgitation of swallowed fluids.⁴² Stupor, coma, and death may occur within 7 to 10 days. In less severe cases, recovery may be slow and may be complicated by the development of myocarditis or neuritis. In mild cases, the membrane sloughs off in 7 to 10 days, and recovery is uneventful.

Laryngeal diphtheria generally reflects a downward extension of the membrane from the pharynx. Rarely laryngeal diphtheria is primary and does not reflect an extension of disease from the pharynx. In these cases, toxicity and signs of toxemia generally are less prominent. Two cases of isolated diphtheritic tracheitis have been reported in the literature.^{13,103} The clinical findings of laryngeal diphtheria are indistinguishable from those of other types of infectious croup. Noisy breathing, progressive stridor, hoarseness, and a dry, barking cough may be noted. Suprasternal, subcostal, and supraclavicular retractions reflect severe laryngeal obstruction, which may be fatal unless alleviated. Occasionally in a mild case, an acute and fatal obstruction may occur because of a partially detached piece of membrane that occludes the airway. In severe cases of laryngeal diphtheria, the membrane may extend downward and invade the entire tracheobronchial tree.

Cutaneous disease, in contrast to pharyngeal disease, is more common in warmer climates and often is caused by nontoxigenic strains. In some countries with tropical and subtropical climates, such as Uganda, Tanzania, Sri Lanka, and Samoa, *C. diphtheriae* has been isolated from 60% of skin lesions in children.⁷⁴ Cutaneous diphtheria is more contagious than respiratory diphtheria. Cutaneous diphtheria may be an important source of person-to-person transmission of diphtheritic organisms and outbreaks in indigenous populations in which overcrowding and poor hygiene are important risk factors.^{12,20,68} The skin lesions

begin as vesicles or pustules that progress to typical ulcers with sharply defined borders, membranous bases, and surrounding erythema and edema. They may be covered with a dark pseudomembrane. The lesions occur most commonly on the legs, feet, and hands. For the first 1 to 2 weeks, the lesions are painful. Spontaneous healing generally takes 6 to 12 weeks, but lesions have been reported to persist for 1 year.⁶⁸

Conjunctival, aural, and vulvovaginal diphtheria also may occur. Conjunctival lesions usually are limited to the palpebral conjunctiva, which appears red, edematous, and membranous. Rarely conjunctival lesions have been associated with corneal erosion.⁹⁹ Diphtheria infections of the ear are characterized by the development of otitis externa with a persistent purulent and frequently foul-smelling discharge.

Clinical presentations other than typical diphtheria have been associated with isolation of the organism from patients with meningitis, endocarditis, osteomyelitis, and hepatitis. In most cases, these infections have occurred in patients with underlying problems, such as structural or valvular heart disease or intravenous drug use, or in individuals from poor socioeconomic backgrounds.^{40,104}

Several cases of septic arthritis caused by nontoxigenic *C. diphtheriae* have been described.^{1,63,104} Afghani and Stutman¹ reported the case of a 27-month-old child who had septic arthritis of the hip and skin lesions on the lower extremities. In this case, the skin lesions were presumed to be the portal of entry for nontoxigenic *C. diphtheriae*. Although the child had received four doses of diphtheria and tetanus toxoids and pertussis vaccines, immunization with toxoid does not provide protection against nontoxigenic strains of *C. diphtheriae*. In this case, the organism was sensitive to penicillin, cefuroxime, cephalothin, and clindamycin but was resistant to oxacillin, an antistaphylococcal antibiotic often used for the treatment of septic arthritis when the causative organism cannot be identified. A similar case was described in an immunocompetent, fully vaccinated 2-year-old child who had skin lesions from which *C. diphtheriae* was isolated. The skin lesions also were assumed to be the portal of entry for the organism because pan-sensitive *C. diphtheriae* were isolated from the skin and the articular aspirate.⁶³

Within a 12-month period, in New South Wales, Australia, four cases of septic arthritis complicating endocarditis caused by the nontoxigenic *gravis* variety of *C. diphtheriae* were reported. In addition, the same strain caused three cases of endocarditis without the development of septic arthritis. Demographic distribution of these seven cases included a 12-year-old boy who died, five patients who were in their 20s, and a patient who was 49 years old. Three of the patients had underlying cardiac abnormalities, and one had a history of intravenous drug use.¹⁰⁴ This same clone of nontoxigenic *C. diphtheriae* was isolated from three patients in Koorie, an aborigine community in Victoria, Australia, who had endocarditis, and five asymptomatic contacts.⁶⁹ Two of the three patients with endocarditis were members of the same family, and one of them had a history of alcohol abuse. The third patient had a septic sternoclavicular joint, in addition to endocarditis, with isolation of the same organism. Nontoxigenic *C. diphtheriae* sepsis can lead to splenic and hepatic abscesses, as reported in a patient with chronic lymphocytic leukemia in British Columbia, Canada.⁷¹

Complications secondary to elaborated diphtheria toxin may affect any system, but myocarditis and involvement of the nervous system are most characteristic. Myocarditis may occur after mild and severe cases of diphtheria. Generally it develops in patients in whom administration of antitoxin is delayed. Myocarditis most commonly appears in the second week of the disease, but it can appear as early as the first or as late as the sixth week of illness. Tachycardia, a muffled S₁, murmurs, and arrhythmias such as atrioventricular dissociation indicate myocardial involvement. Echocardiography may show left ventricular dysfunction.^{3,61,80} Although some cases may result in cardiac failure, most myocardial complications are temporary.

Neurologic complications appear after a variable latent period. Approximately 75% of all patients with severe diphtheria develop neuropathies. The incidence of neurologic sequelae has been shown to correlate with the severity of respiratory symptoms; 20% of all patients with respiratory problems develop polyneuritis. Neurologic complications from diphtheria infections predominantly are bilateral, are motor rather than sensory, and usually resolve completely. Paralysis of the soft palate

is the most common occurrence and generally appears in the third week. It is manifested by a nasal quality in the voice, nasal regurgitation, and difficulty swallowing. Ocular paralysis usually occurs around the fifth week of illness and is characterized by blurring of vision and difficulty with accommodation. Internal strabismus also may be noted. Paralysis of the diaphragm, peripheral neuropathy involving the limbs, and loss of deep tendon reflexes likewise are reported as complications of diphtheria. When they occur, along with an elevated cerebrospinal fluid protein, the syndrome is clinically indistinguishable from Guillain-Barré syndrome.

Rarely, 2 or 3 weeks after the onset of illness, involvement of the vasomotor centers results in hypotension and cardiac failure. Gastritis, hepatitis, nephritis, and hemolytic-uremic syndrome also have been reported as complications of diphtheria.¹⁰²

Information on the effects, if any, of diphtheria on the fetus during pregnancy is sparse. El Seed and associates⁴⁷ reported a case of pharyngeal diphtheria in a pregnant woman that occurred during the first trimester of pregnancy. Apart from vaginal bleeding, no complications of pregnancy were noted. Severe diphtheritic toxemia in the mother was characterized by quadriplegia, from which she fully recovered. A physically normal female infant was delivered at term. In this single case, severe diphtheritic toxemia during pregnancy was not associated with any teratogenic effect in the fetus and did not impair intrauterine fetal growth.

DIAGNOSIS

The diagnosis of diphtheria should be based on clinical findings because any delay in initiating therapy poses a serious risk to the patient. Isolation of the organism is used to confirm the clinical diagnosis. Material obtained from beneath the membrane, where organisms are concentrated most highly, or a portion of the membrane itself should be obtained for culture.^{5,33}

C. diphtheriae is relatively resistant to drying. The use of a nonnutritive, moisture-reducing transport medium helps prevent the overgrowth of other microorganisms. The laboratory should be notified about the possibility of diphtheria so that appropriate culture media are inoculated. A Löffler slant, a tellurite plate, and a blood agar plate should be inoculated. Tellurite-containing media inhibit the growth of normal oral flora, allowing *C. diphtheriae* to grow into characteristic black colonies. Other corynebacteria, staphylococci, and yeast also can reduce tellurite and grow into black colonies.³⁸ Although examination of direct smears of colonies or diphtheritic lesions remains an important supplement to clinical examination, it often is inaccurate. Screening the colonies from the tellurite plate for catalase, urea, nitrate, pyrazinamidase, and cystinase is important. Most biotypes of *C. diphtheriae* are catalase positive, urease negative, nitrate positive (except biotype *belfanti*), pyrazinamidase negative, and cystinase positive.⁴³

All diphtheria bacilli that are recovered should be tested for toxigenicity. In 1949, the Elek immunoprecipitation assay replaced in vivo testing for toxigenicity using guinea pigs or rabbits.⁴⁶ The Elek test is based on gel diffusion and immunoprecipitation of toxin from organisms inoculated onto agar adjacent to an antitoxin-containing well. A strain that is positive for toxin is indicated by the formation of a precipitin band between the toxin and antitoxin.^{44,46} The Elek test takes 48 hours to yield results on the toxigenic nature of a *C. diphtheriae* strain. A modified Elek test that consists of placement of an antitoxin-impregnated disk onto an agar plate surrounded by inoculates of clinical specimen and positive control has been described. In contrast to the conventional Elek test, the modified test has the advantage of using "spot" inoculations of numerous colonies directly from the primary plate. In addition, the modified Elek test has fewer false-positive and false-negative results and yields results more rapidly (16 to 24 hours).⁴³

A rapid enzyme immunoassay is another test for detection of diphtheria toxin. This method uses equine polyclonal antibody to capture the diphtheria toxin and an alkaline phosphatase-labeled monoclonal antibody to detect fragment A of the toxin. It is a rapid test that takes 3 hours and has a limit of detection of 100 pg/mL.⁴⁸

Rapid testing for diphtheria toxin by PCR specific for the A or B portion of the toxin gene, *tox*, is sensitive and has produced positive results in specimens stored for 12 months before performing the

assay.^{7,74,75,91,92,94} The absence of the *tox* gene by PCR excludes the diagnosis of diphtheria. PCR may give false-positive results, however, because it does not differentiate between partial or nonfunctional *tox* genes and functional *tox* gene products. An increasing number of cases of non-toxigenic diphtheria that are positive for the *tox* gene by PCR have been reported from Ukraine and Russia.^{58,83}

The immune status of patients can be determined by toxin neutralization in Vero cells.⁸⁸ This method is used frequently, although it is difficult to standardize and relies heavily on individual interpretation of results. Enzyme-linked immunosorbent assay is a more rapid and quite sensitive method, but it detects some nonspecific antibodies; when antitoxin levels are in the low range, the assay may generate falsely elevated results.⁸⁶ Finally a delayed fluorescence immune assay method was developed by Aggerbeck and colleagues² in 1996 and has been reported to have good sensitivity, specificity, and reproducibility.¹⁶ Levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective. A skin-testing method, the Schick test, also has been used to assess immunity.

The Schick test was used previously to determine the immune status of the patient. It is not helpful in establishing an early diagnosis because it cannot be read for several days, and currently it is not widely used. In the Schick test, a measured amount of purified diphtheria toxin (0.1 mL) is injected subcutaneously. A hypersensitivity reaction indicates an inadequate presence of antitoxin. A toxoid control also is injected, in the opposite arm, to help distinguish between a reaction to toxin and a reaction to other antigens in the toxin preparation.

Other laboratory studies are of little diagnostic value. The white blood cell count may be normal or elevated. Rarely anemia develops as a result of rapid hemolysis of red blood cells. Examination of cerebrospinal fluid may reveal a minimal elevation of protein and, rarely, a mild pleocytosis in patients with diphtheritic neuritis. Hypoglycemia, glucosuria, or both may occur and reflect hepatic toxicity. An elevation in blood urea nitrogen may develop in patients with acute tubular necrosis. An electrocardiogram should be obtained and may reveal ST-segment and T-wave changes or arrhythmias indicative of myocarditis.

Differential Diagnosis

Mild forms of nasal diphtheria in a partially immunized host may resemble the common cold. When the nasal discharge is more serosanguineous or purulent, nasal diphtheria must be distinguished from a foreign body in the nose, sinusitis, adenoiditis, or the sniffles of congenital syphilis. Careful examination of the nose with a nasal speculum, sinus radiographs, and appropriate serologic tests for syphilis are helpful in excluding these disorders.

Tonsillar or pharyngeal diphtheria must be differentiated from streptococcal pharyngitis. Generally streptococcal pharyngitis is associated with more severe pain on swallowing, higher temperature, and a nonadherent membrane limited to the tonsils. In some patients, pharyngeal diphtheria and streptococcal pharyngitis coexist.

Tonsillar and pharyngeal diphtheria also must be differentiated from infectious mononucleosis (lymphadenopathy and splenomegaly are common findings, atypical lymphocytes are generally present, and heterophile antibody may be present), nonbacterial membranous tonsillitis (white blood cell count generally is low, throat cultures reveal normal flora, and the course is unaffected by antibiotics), primary herpetic tonsillitis (presence of gingivitis, stomatitis, and discrete lesions of the tongue and palate may be helpful), Vincent angina (may be indistinguishable), and thrush (constitutional symptoms are absent, and lesions are present on the buccal mucosa and tongue). Tonsillar and pharyngeal diphtheria also must be differentiated from blood dyscrasias such as agranulocytosis and leukemia (complete blood count and bone marrow study are helpful); post-tonsillectomy faucial membranes (membranes are stationary and do not spread); and oropharyngeal involvement by toxoplasmosis, *Arcanobacterium*, cytomegalovirus, tularemia, and salmonellosis (associated signs and symptoms and appropriate cultures and serologic tests may be diagnostic).⁵⁵

Laryngeal diphtheria must be differentiated from spasmodic or nonspasmodic croup; acute epiglottitis; laryngotracheobronchitis; bacterial tracheitis (particularly staphylococcal); aspirated foreign bodies;

peripharyngeal and retropharyngeal abscesses; and laryngeal papillomas, hemangiomas, or lymphangiomas. A careful history, followed by careful visualization in the hospital under controlled conditions, aids in making a correct diagnosis.

PREVENTION

Diphtheria is prevented on a community-wide basis most effectively by active immunization. Diphtheria toxoid is available in combination with tetanus toxoid as pediatric DT or adult Td and in combination with acellular pertussis as DTaP and Tdap. Combination regimens with DTaP and inactivated poliovirus and hepatitis B (Pediatrix) and inactivated poliovirus and *Haemophilus influenzae* type B (Pentacel) are also available. Pediatric formulations of diphtheria toxoid vaccines contain three to four times more diphtheria toxoid but the same tetanus toxoid in contrast to the adult formulations. Children younger than 7 years should be given the pediatric formulations of vaccine, whereas children older than 7 years should receive the adult Td. Two forms of Tdap are available: Boostrix, which is approved for children beginning at age 10 through 65 years or older, and Adacel, which is approved for individuals 11 to 64 years old.^{22,26–29}

Primary immunization is carried out conveniently and effectively by giving diphtheria and tetanus toxoids and pertussis vaccine, DTaP, at 2, 4, and 6 months of age, with booster doses given at 15 to 18 months and again when the child is 4 to 6 years of age. Booster doses with the adult type of diphtheria and tetanus toxoids adsorbed (Td) should be given at 10-year intervals to all immunized individuals. Current recommendations are to give Tdap as the first booster dose in patients who are 11 to 12 years old and to anyone older who has not received a dose of Tdap.³⁰ Td and Tdap contain 2 to 2.5 flocculation units (Lf) diphtheria toxoid per dose in contrast to 7 to 25 Lf in the pediatric diphtheria, tetanus toxoid, and pertussis vaccine preparations (DTaP and DT). Primary immunization of children older than 7 years may be performed with Td. Two doses are given intramuscularly at least 4 weeks apart, with a booster dose provided 1 year later. Children and adults who are severely immunocompromised or undergoing long-term hemodialysis should use the standard immunization schedule, although response may be suboptimal.^{51,56,76}

Most local and systemic reactions to the diphtheria and tetanus toxoids and whole cell pertussis vaccine (DTP), including fever, were related to the pertussis component.^{10,37} Administration of tetanus and diphtheria toxoids is not followed by the high incidence of reactions associated with the use of pediatric DTP vaccines. At least one study showed that 7.5 Lf toxoid can be given safely to adults without a higher risk for reactions occurring.¹⁴ Primary immunization against diphtheria for infants with progressive neurologic disorders and completion of the primary immunization series in patients who had experienced an untoward reaction to an earlier DTP vaccine injection may be performed with diphtheria and tetanus toxoids rather than diphtheria and tetanus toxoids and pertussis vaccine.⁴

A report of 97 preterm infants who received diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) (94 of these infants also received *H. influenzae* type B vaccine) showed that most infants tolerated the vaccination without side effects, although a subgroup of infants with very low birth weight (mean, 873 g) had either a recurrence or an increase in the number of apneic and bradycardic episodes in the 48 hours after receiving vaccination. The apneic and bradycardic episodes were present before immunization in every case.¹⁰⁰

Booster doses of tetanus and diphtheria toxoids should be given at 10-year intervals to all immunized individuals. The CDC Advisory Committee on Immunization Practices now recommends that all adults aged 19 years and older who have not received a dose of Tdap should receive a single dose.^{31,84} A recent update recommends a dose of Tdap during every pregnancy.³² As mentioned earlier, levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective.

Diphtheria immunization is not always followed by complete protection.⁷⁸ Immunization is directed against the phage-mediated toxin, not against infection. Fully immunized individuals may be carriers or may have disease caused by nontoxicogenic strains. An investigation conducted

during an epidemic in Texas showed no statistical difference in the risk for diphtheria infection developing in individuals with full, lapsed, inadequate, or no previous diphtheria immunization; however, a 30-fold increased risk for development of symptomatic diphtheria in individuals with no immunization and an 11.5-fold increase in individuals with inadequate immunization were noted.⁸⁷

The most important health problem in the United States today is inadequate immunization of the population. Immunization rates in adults are poorer than those in infants and children because of failure to maintain adequate immunity through appropriate booster immunization. A 70% to 80% immunization level is thought to be required to prevent epidemic spread.³⁶

Prevention of diphtheria also depends on management of the contacts of known cases of diphtheria and carriers of the organism and on isolation of patients to minimize the spread of disease. Individuals at risk for contracting the disease from the index case include those who have had close respiratory or physical contact or prolonged close proximity with the infected individual, including members of the index case's household.¹⁷ Specifically, family members who share body towels and cups or eating utensils, share a bed or a bedroom with more than two people, or take a bath less than once per week have a significantly greater risk for contracting the disease from the infected patient. A history of eczema in the contact also has been associated with a significantly increased risk for contracting diphtheria from the index case.⁹⁷ The patient is infectious until diphtheria bacilli no longer can be cultured from the site of infection. Two or three consecutive negative cultures at least 24 hours apart are required, and antibiotic therapy must be complete for 24 hours before the patient is released from isolation. If obtaining cultures is impossible, isolation may be ended after the completion of 14 days of appropriate antibiotic treatment.⁶

Cultures should be taken from the nose and throat of all close contacts, who should be kept under surveillance for 7 days (surveillance as an outpatient is acceptable).⁵ Regardless of their immunization status, contacts should be treated with a single intramuscular dose of benzathine penicillin G 600,000 U for individuals weighing less than 30 kg and 1.2 million U for individuals weighing more than 30 kg or a 7-day course of erythromycin 40 to 50 mg/kg per day (maximum 2 g/day) divided into four doses.⁵ The immune status of each contact should be determined; individuals for whom immune status is inadequate, including individuals who have had the primary series but more than 5 years has elapsed since they received their last booster dose, should receive an injection of diphtheria toxoid. In addition, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.⁶

Asymptomatic carriers who previously were not immunized against diphtheria should have cultures taken, receive diphtheria toxoid and penicillin or erythromycin (as described earlier), and be seen daily by a physician. Asymptomatic contacts who are found to carry a toxigenic strain should be subjected to the same isolation and treatment measures as the index case.⁶ If daily surveillance is impossible, benzathine penicillin is preferred over erythromycin for treatment because failure to adhere to an oral drug regimen is a concern. If a contact is experiencing symptoms when seen, treatment of diphtheria is indicated. It is important to initiate prophylactic therapy in contacts who have not been immunized before the results of culture are received. Management of carriers is described in the next section. Contacts whose occupations involve close contact with unimmunized children or food handling (especially milk) should refrain from working until cultures are confirmed to be negative.⁶

TREATMENT

Treatment of diphtheria is predicated on neutralization of free toxin and eradication of *C. diphtheriae* or *C. ulcerans* with antibiotics. Disease caused by *C. ulcerans* should be treated in the same manner as disease caused by *C. diphtheriae*.^{3,24} The decision to administer equine antitoxin should be based on the site and size of the membrane, the degree of toxicity, and the duration of illness and should be made clinically as soon as possible.¹⁵

Antitoxin can neutralize circulating toxin or toxin that is absorbed onto cells, but is ineffective when cells have been penetrated. Early treatment is essential to limit tissue damage. An adequate dose of antitoxin must be administered intravenously as early as possible to neutralize all free toxins. A single dose is used to avoid the risk for developing sensitization from repeated doses of horse serum. Tests for sensitivity to horse serum must be performed before antitoxin is administered. Antitoxin and its indications for use as well as instructions for sensitivity testing and administration are available through the CDC (Emergency Operations Center, 770-488-7100; www.cdc.gov/diphtheria/dat.html).⁵ The antitoxin dosage is empirical. Pharyngeal or laryngeal disease of 48 hours' duration or less should be treated with 20,000 to 40,000 U, nasopharyngeal disease with 40,000 to 60,000 U, and severe pharyngeal or laryngeal diphtheria with 80,000 to 120,000 U of antitoxin. The last dose also should be given to patients with mixed clinical symptoms and to patients with brawny edema or disease of longer than 48 hours' duration. The value of antitoxin in the treatment of cutaneous disease is debated, but some experts recommend 20,000 to 40,000 U because toxic effects have been reported.⁵ The use of intravenous immunoglobulin (IgIV) for therapy of respiratory or cutaneous diphtheria has not been approved or evaluated for efficacy. A human monoclonal antibody to replace equine diphtheria antitoxin is under development and holds promise as a potential therapeutic agent.¹⁰¹

Although antibiotics are not a substitute for treatment with antitoxin, they should be given when diphtheria is suspected clinically. Penicillin and erythromycin are still effective against most strains of *C. diphtheriae*. Penicillin and erythromycin also are effective in eradicating group A hemolytic streptococci, which may complicate 30% of cases of diphtheria. Treatment consists of a 14-day course of penicillin or erythromycin. Penicillin may be given as aqueous penicillin G 100,000 to 150,000 U/kg per day in four divided doses intravenously or as procaine penicillin 25,000 to 50,000 U/kg per day (maximum of 1.2 million U) in two divided doses intramuscularly. Patients who are sensitive to penicillin should be given erythromycin in a daily dosage of 40 to 50 mg/kg (maximum of 2 g/day) in four divided doses for 14 days. When the patient is able to tolerate oral medications, erythromycin or penicillin V may be used in place of the intravenous antibiotics.⁵

Follow-up cultures should be obtained at least 2 weeks after antibiotic therapy is completed; if they are positive, erythromycin should be given for an additional 10 days.⁵ Some resistance to erythromycin has been observed, but it is uncommon, and its epidemiologic significance is unknown.^{5,6} Penicillin is recommended as first-line treatment in Vietnam, based on sensitivity data.⁷³ Amoxicillin, rifampin, and clindamycin provided in appropriate dosages also may be effective. Lincomycin and tetracycline have proved to be less effective, and cephalixin, oxacillin, and colistin have been shown to be ineffective against *C. diphtheriae*. The endpoint of therapy is two or three consecutive negative cultures at least 24 hours apart. In addition to receiving antibiotic therapy, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.⁵

The carrier state has been treated effectively with a single intramuscular dose of benzathine penicillin G 600,000 U for children weighing less than 30 kg or 1.2 million U for individuals weighing 30 kg or greater or oral erythromycin 40 to 50 mg/kg per day for children and 1 g/day for adults for 7 to 10 days.⁵ Carriers should have repeat pharyngeal cultures performed a minimum of 2 weeks after antibiotic therapy is complete; if the repeat cultures are positive, carriers should receive an additional course of antibiotics.

Treatment of deep infections caused by nontoxigenic *C. diphtheriae* can be accomplished with a wide variety of susceptible agents. Endocarditis with these organisms treated with either a β -lactam alone or in combination with an aminoglycoside has been associated with favorable outcomes.⁹⁰

Supportive Treatment

Bed rest is extremely important and should be required for 2 to 3 weeks. Serial electrocardiograms should be obtained two or three times each week for 4 to 6 weeks to detect myocarditis as early as possible. Absolute bed rest must be enforced if myocarditis is detected, because sudden death has been precipitated by excessive activity. A

patient with myocarditis may receive digitalization if congestive heart failure develops. Digitalization for arrhythmias caused by diphtheria may be contraindicated, however. In severe disease, prednisone 1 to 1.5 mg/kg per day for 2 weeks has been shown to lessen the incidence of myocarditis.

Hydration should be maintained, and a high-calorie liquid or soft diet should be provided. Secretions should be suctioned as needed to prevent aspiration. Palatal and pharyngeal paralysis increases the risk for aspiration occurring, so gavage via a nasogastric tube is indicated in these patients.

The quality of the voice and the gag reflex should be checked regularly for assessment of progression of the disease. Laryngeal diphtheria may require relief of obstruction with a tracheostomy. This procedure should be performed before the patient has become exhausted.

Adequate immunity does not develop in at least half of patients who recover from diphtheria, and they remain subject to reinfection. Immunization is indicated after the patient recovers.

PROGNOSIS

Many factors affect the prognosis in cases of diphtheria, the most important being the immunization status of the host. Morbidity and mortality rates are increased significantly in patients who are unimmunized or inadequately immunized. The rapidity with which medical care is sought and the diagnosis of diphtheria is suggested has a great impact on outcome. If specific treatment is provided on the first day of disease, the mortality rate may be reduced to less than 1 percent; delay in providing treatment until day 4 may be associated with a 20-fold increase in the mortality rate.

The virulence of the infecting organism and the location of infection are important prognostic factors. Infection with a nontoxigenic *C. diphtheriae* strain may cause disease but does not lead to myocarditis, neuritis, and other toxin-related phenomena. Toxigenic disease may vary from mild to severe. In cases of mild diphtheria, membrane sloughing and full recovery generally occur within 7 days. Disease caused by toxigenic *gravis* strains tends to be more severe and carries a poorer prognosis. Although diphtheria may affect the skin, nasopharynx, and other mucous membranes, involvement of the larynx heralds a more complicated course. Laryngeal diphtheria increases the risk for development of airway obstruction and promotes systemic absorption of the toxin. These patients require close monitoring of respiratory function and for involvement of other organ systems. Laryngeal diphtheria is more likely to be fatal in infants.

Few laboratory parameters indicate the severity of diphtheria. The development of megakaryocytic thrombocytopenia and leukocytosis with counts of greater than 25,000 cells/mm³ has been associated with a poor outcome.

The prognosis in a patient with diphtheria remains guarded until recovery is complete. At any time during the course of the illness, complications such as laryngeal obstruction, shock, and ventricular fibrillation may occur suddenly and unexpectedly. In patients with myocardial involvement, permanent damage to the heart, specifically fibrosis, may occur and lead to later complications. In addition, potentially severe neurologic manifestations, such as phrenic nerve paralysis, may appear late in the course of the disease.

Persistence of *C. diphtheriae* may be noted in the nasopharynx of 5% to 10% of convalescing patients. Recovery from diphtheria is followed by immunity that is demonstrable for at least 1 year after illness in 50% of patients. Second attacks are rare; nonetheless, immunization should be performed after the patient recovers.

Before the use of antitoxin and the availability of antibiotics, the mortality rate from diphtheria was 30% to 50%. Death was most common in children younger than 4 years old and was the result of suffocation. At present, the worldwide mortality rate is 5% to 10%, with no clear association with age.

Anthrax

Morven S. Edwards

Anthrax, also known as charbon, woolsorter's disease, and ragpicker's disease, is a toxigenic disease of herbivores for which humans are an incidental host. The term *anthrax*, derived from the Greek *anthrakos*, or "coal," refers to the black eschar characteristic of cutaneous anthrax. The three clinical manifestations of anthrax are cutaneous, which accounts for 95% of infections in the United States; inhalation; and gastrointestinal. Each can occur in children,³⁸ and all can be complicated by meningitis.

HISTORICAL ASPECTS

Anthrax has been recognized since antiquity. The earliest reference to a disease thought to be anthrax is a description in Exodus of the plague that caused the death of all of the Egyptians' cattle. Hippocrates described carbuncles that are thought to represent the cutaneous form of anthrax. An account of anthrax in animals is detailed in the third of the Roman poet Virgil's four *Georgics*.³⁵ In the early 17th century, an anthrax pandemic referred to as "Black Bane" caused 60,000 human deaths in Europe. By the 18th century, several excellent descriptions of the clinical disease in humans had been published.

Bacillus anthracis has a unique niche in infectious diseases. The organism, seen microscopically by Delafond in 1838, was isolated and cultivated in 1877 by Koch, who showed its proliferation in vivo, establishing a model for the causation of infectious disease. In 1881, both Pasteur and Greenfield⁴⁰ showed that a live-attenuated anthrax bacillus vaccine provided protection against subsequent challenge in animals, demonstrating the efficacy of immunization to prevent an infectious disease. In the late 1800s, anthrax was proved to be the cause of inhalation anthrax, contracted by factory workers handling anthrax-contaminated animal hides.

During World War I, *B. anthracis* was manufactured as an agent for biologic warfare. Because anthrax transmitted by inhalation is usually fatal and *B. anthracis* spores are stable in the environment, anthrax continues to be a focus of biologic warfare research programs. The accidental release of anthrax spores from a military research facility in Sverdlovsk in the former Soviet Union in 1979 resulted in at least 68 inhalation anthrax deaths.³¹

The first confirmed outbreak associated with intentional anthrax release in the United States occurred in October 2001.²³ Anthrax spores were disseminated by mail, resulting in five deaths from inhalation and 22 total cases of cutaneous and inhalation anthrax. Envelopes containing anthrax spores were sent through the US Postal Service to offices of newspaper and broadcast media and US senators. The spores were "weaponized," or finely milled, and treated with chemicals to prevent clumping so they dispersed when the envelopes were opened and leaked from sealed envelopes as they passed through mail-sorting machines. A single anthrax strain was implicated. Outbreak-related expenditures

exceeded billions of dollars and revealed the potential impact of a bioterrorism event.^{7,13} It is estimated that the aerosolized release of 100 kg of anthrax spores upwind of Washington, DC, could result in 130,000 to 3 million deaths.

A distinct form of anthrax, injectional anthrax, emerged in drug users in Europe in 2009 and has been attributed to contaminated heroin.¹

BACTERIOLOGY

B. anthracis is an aerobic, nonmotile, spore-forming rod in the family Bacillaceae. Optimal growth occurs at 36°C in nonselective media. Colonies are gray-white, rough, and flat and can have comma-shaped projections caused by the outgrowth of chains of bacilli from the edges of the colony, giving it a "Medusa head" appearance. Individual colonies are 4 to 5 mm in diameter with a ground-glass appearance and exhibit tenacity or a "beaten egg white" appearance when lifted with an inoculating loop. The capsule, a γ -linked poly-D-glutamic acid, can be produced in blood or by culture in carbon dioxide. Gram stain reveals large, square-ended, gram-positive rods singly or in short chains without a visible capsule. The equatorial or paracentral spores are invisible in smears fixed promptly after collection. After 24 to 48 hours of aerobic incubation, strands of rods are arranged in "boxcar" or "bamboo" fashion and sporulation occurs. Small numbers of bacteria are pathogenic for mice, guinea pigs, and rabbits, and death usually occurs 2 to 5 days after inoculation. Genotyping methods are available to determine molecular relatedness of clinical isolates and their geographic origin.³⁰

EPIDEMIOLOGY AND TRANSMISSION

Domestic herbivores—cattle, sheep, horses, goats, and swine—are the most important agricultural sources of anthrax, but all domestic and many wild animals can serve as hosts. Animals are infected by ingestion of spores from infected pastures. Spores germinate in vivo, and death, associated with massive septicemia, usually occurs in 1 or 2 days. Anthrax is endemic in areas where an animal-soil-animal cycle is established because the spores can survive indefinitely in a dry environment. Uncultivated soil with a pH greater than 6.0 and ambient temperature greater than 15.5°C provides an environment favorable for persistence of spores.

An estimated 20,000 to 100,000 human cases of anthrax occur yearly.³⁶ Regions of high endemicity include Central and South America, southern and eastern Europe, Asia, Africa, the Caribbean, and the Middle East. The number of human cases probably correlates with the enzootic status of the disease in livestock in these countries. Familial clustering can occur in association with exposure to diseased animals. Children who live in endemic areas can contract cutaneous anthrax from direct

animal contact.³² Cases of illness were identified in four states and in Washington, DC, during the 2001 bioterrorism-related outbreak.

The incidence of human anthrax in the United States has decreased markedly since the early 1900s, when more than 100 cases were reported annually. Cutaneous infections are reported sporadically. Cases often are associated with exposure to contaminated animal products in commercial preparations, but exposure to indigenous animal anthrax does occur.³⁹ Two members of a farmer's family ate hamburgers made from an anthrax-infected steer in Minnesota in 2000. The family members received antibiotic prophylaxis and anthrax vaccine and remained well.¹⁴

Direct contact with contaminated animal meat or carcasses or with contaminated animal products, such as hides, hair, wool, bone meal, and animal feed, are sources of transmission of anthrax spores to humans. Children of industrial workers have acquired infection, presumably from contact with their parents' contaminated clothing. Processed products, such as shaving brushes and saddle blankets, have been implicated as sources of infection. Use of contaminated goat hides from West Africa caused cutaneous anthrax in a drum maker in Connecticut and, through his work clothing or objects from his shed, led to cutaneous anthrax in his 8-year-old child.¹⁶ Cutaneous anthrax is transmitted by deposition of spores or bacilli into abrasions or cuts in the skin. Blood-sucking insects, including mosquitoes and stable flies, can be vectors.⁴¹

The mode of acquisition may be difficult to determine in children; in one child with cutaneous anthrax, the only potential exposure was proximity to a bone meal factory that he walked past on his way to school.²⁷ Tying the umbilicus with a dirty thread was the presumed portal of entry for a neonate with *B. anthracis* sepsis.³² Rubbing with contaminated fingers or deposition by an insect vector can lead to cutaneous involvement of the eyelids.⁴³ Discharge from cutaneous lesions theoretically is infectious, but person-to-person transmission has not been confirmed. Skin-to-skin contact through his mother's exposure at her workplace was proposed as the route of transmission to an infant in the US bioterrorism-related outbreak.²⁰ Maternal anthrax has been associated with preterm delivery.²⁴

Inhalation anthrax results from inhalation of spores. The estimated infectious dose in humans is 8000 to 50,000 spores. Cases of inhalational anthrax in the United States have occurred in a weaver whose imported yarn was contaminated and a drum maker whose imported hand-dried animal hide was contaminated with *B. anthracis*.^{9,15} In some patients no specific source is identified, as with a man who acquired inhalation anthrax while vacationing through states in which animal anthrax is sporadic or enzootic.²¹ Eleven adults acquired inhalational anthrax during the 2001 bioterrorism outbreak of anthrax in the United States. Gastrointestinal anthrax usually is caused by ingestion of contaminated meat but has occurred after exposure to a contaminated animal-hide drum.^{17,25} Neonates can contract anthrax meningitis if a mother is bacteremic at the time of delivery.

PATHOGENESIS AND PATHOLOGY

Anthrax toxicity results from the capsule and from the activity of three polypeptides—protective antigen, edema factor, and lethal factor—that combine to form two exotoxins: lethal toxin and edema toxin. Protective antigen is integral to the action of both toxins. Toxin entry into cells is initiated when protective antigen binds to membrane receptors of susceptible cells. Two related proteins, tumor endothelial marker 8 and capillary morphogenesis protein 2, function as receptors. Cleaved protective antigen oligomerizes and a heptamer of protective antigen provides binding sites for edema factor or lethal factor. The complex is endocytosed as edema toxin or lethal toxin.

Edema factor is a calmodulin-dependent adenylate cyclase that increases intracellular cyclic adenosine monophosphate levels and is responsible for the massive edema that occurs in cutaneous anthrax.²⁸ Lethal factor is a metalloproteinase that cleaves mitogen-activated protein kinase-kinases so that they are unable to activate their downstream substrates, the mitogen-activated kinases.¹⁹ Lethal factor stimulates production of tumor necrosis factor- α and interleukin-1 β . The capsule of *B. anthracis* contributes to virulence by inhibiting phagocytosis.^{23,42}

Cutaneous infection is initiated when anthrax spores are ingested at the site of entry by macrophages and germination occurs in skin

tissues. Production of toxin results in local edema. Regional lymphangitis and lymphadenopathy can occur.¹⁸ Interstitial edema, lymphatic dilation, and thrombosis and necrosis of blood vessels are characteristic microscopic features of cutaneous anthrax lesions. Erythrocytes extravasate freely into interstitial fluid. Few neutrophils or other inflammatory cells are present unless a lesion is infected secondarily. Hemorrhagic lymphadenitis involving regional lymph nodes occurs in all forms of anthrax.

In inhalation anthrax, spores entering alveoli are ingested by alveolar macrophages and dendritic cells and carried to mediastinal lymph nodes, where they germinate. Inhalation anthrax is not pneumonia, although primary focal hemorrhagic necrotizing pneumonia can occur at the pulmonary portal of entry.² Massive hemorrhagic mediastinal lymphadenitis can block lymphatic drainage routes and can be causally related to the pulmonary edema, respiratory distress, and systemic disease observed clinically.

Gastrointestinal anthrax results from ingestion of spores or vegetative bacilli in contaminated meat. The primary sites of infection are the epithelium of the stomach or bowel wall.⁸ Edema and necrotic ulcers of the mucosa of the gastrointestinal tract, especially the ileum or cecum, are characteristic findings. Dissemination to the CNS can occur by hematogenous or lymphatic routes from any site of primary involvement. Hemorrhage involving the meninges and intense arteritis are uniform findings in patients who die of anthrax meningitis.

Injectional anthrax results from direct injection or "skin popping" among persons who become infected by injecting heroin. At least 70 confirmed cases have been attributed to contaminated heroin distributed throughout Europe.¹

CLINICAL MANIFESTATIONS

Cutaneous Anthrax

The lesions of cutaneous anthrax occur mainly on exposed areas of the body.³ In one report, the distribution in young children was 52% of lesions on the head and neck, 28% on the trunk, and 20% on the extremities, whereas in older children the distribution was 70% on the head and neck, 16% on the trunk, and 14% on the extremities.²² Spores are introduced through abraded or injured skin. Children can have one or several lesions, and they are associated with regional adenitis.²⁹ After an incubation period of 2 to 5 days, a small, nontender, but often pruritic, papule develops at the site of inoculation. The lesion progresses within 36 hours to a serous or serosanguineous vesicle with surrounding nonpitting edema. Satellite vesicles, sometimes referred to as a "pearly wreath,"⁴³ can be seen occasionally.

The lesion undergoes central necrosis, and a 1- to 3-cm black eschar with well-defined margins forms 1 week to 10 days after onset of illness (Fig. 91.1).³⁴ The term *malignant edema* is used to describe severe lesions, particularly those involving the head and neck, which can be associated with systemic toxicity and occlusion of the airway. Small children can appear acutely ill with a temperature of 39° to 40°C (102.2° to 104°F) and leukocytosis with counts of 20,000 to 30,000 cells/mm³.^{20,27} Bacteremia is uncommon. The edema usually resolves within 2 to 3 days, but separation of the eschar can take several weeks, and healing occurs with variable central scarring.

Inhalation Anthrax

Inhalation anthrax is a biphasic illness. Symptoms in the initial stage—malaise, low-grade fever, myalgia, and nonproductive cough—are nonspecific and resemble an upper respiratory tract illness. Adults who have inhalational anthrax more often present with tachycardia, high hematocrit, and low albumin and sodium levels and less often with myalgias, headache, and nasal symptoms than do adults who have influenza-like illnesses.²⁶ After several days of illness, dyspnea and hypoxemia initiate onset of the second stage, which usually terminates fatally within 24 hours. Chest radiographs can show a widened mediastinum with smooth borders and evidence of hemorrhagic mediastinitis and large, often bloody pleural effusion. Pulmonary infiltrates usually are the result of superimposed bacterial infection. In the more recent cases from the United States, computed tomography of the chest showed the characteristic findings of hemorrhagic mediastinal and hilar lymph nodes and mediastinal edema and pleural effusions.⁷

FIG. 91.1 Cutaneous anthrax with associated massive submental edema. The lesion is located at the site of a small, initially trivial laceration that served as the portal of entry for the anthrax endospores. The patient received ampicillin and recovered completely. (Courtesy M. Thomas Casey, MD.)

Gastrointestinal Anthrax

Gastrointestinal anthrax can manifest as oropharyngeal or intestinal disease.¹² Each has an incubation period of 2 to 5 days after the ingestion of contaminated meat. The oropharyngeal form results in an oral or esophageal ulcer.^{8,23} Presenting features include fever, severe sore throat, neck swelling caused by edema and enlargement of the cervical lymph nodes, dysphagia, and respiratory difficulty. Lesions on the tonsils or posterior oropharynx progress over 1 to 2 weeks from edema to a pseudomembrane-covered ulcer. Oropharyngeal anthrax, although uncommon, has a more favorable prognosis than intestinal anthrax.

Initial features of intestinal anthrax are fever, nausea, anorexia, vomiting, and diffuse abdominal pain that progresses rapidly to severe abdominal pain with rebound tenderness. Vomiting of blood-tinged or coffee ground–like material and melena are common and are caused by ulceration of the intestinal mucosa.^{8,23} Pain decreases, and massive ascites develops within 24 to 48 hours. Abdominal radiographs show edematous loops of bowel and decreased air. If the abdomen is explored, findings include enlarged, erythematous mesenteric lymph nodes and straw-colored to purulent ascitic fluid in which organisms are readily visible.⁴ Death usually occurs in association with significant blood loss, electrolyte imbalance, and shock. If the patient survives, the edema and melena subside in 10 to 14 days.

Injection Anthrax

Direct injection has resulted in a distinct clinical presentation. Extensive painless edema occurs at the injection site. There is a notable absence of the eschar typical of cutaneous anthrax. Extensive tissue involvement can necessitate surgical debridement. Biphasic illness, with initial recovery followed by deterioration with systemic findings occurs in some patients.¹

Meningitis

Most reports of anthrax meningitis are associated with cutaneous disease, likely owing to the higher frequency of cutaneous disease. Anthrax can disseminate to the meninges from any site of primary involvement. In

the 2001 bioterrorism event, one adult with inhalation anthrax presented with meningitis, and several others had features suggestive of CNS involvement.³³ In one group of 70 patients with anthrax meningitis who ranged from younger than 1 to 71 years of age, no primary focus was evident in 12%.

Anthrax meningitis is characterized by a fulminant, rapidly progressive course. Initial symptoms include intense headache, nausea and vomiting, myalgia, chills, dizziness, and, occasionally, a petechial rash. Meningismus is usually present, but not invariably, because of the acuity of the course. Progressive neurologic deterioration with delirium, convulsions, and coma can occur in hours or over the course of 2 to 4 days. Overall survival is approximately 5%, but survival without sequelae has been reported in children.^{33,37,38}

Examination of cerebrospinal fluid (CSF) reveals gross or microscopic hemorrhage, leukocytosis consisting predominantly of neutrophils, elevated protein, and depressed glucose. Gram-positive rods are easily visible on smears of CSF. Peripheral leukocytosis is common, and the white blood cell count can be 60,000 to 80,000 cells/mm³. Blood cultures yield the organism in 70%, and CSF cultures are positive in virtually 100% of patients. Neuroimaging findings are notable for multiple hemorrhages in the ventricles, subarachnoid space, and deep gray matter.³³

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

B. anthracis can be visualized by direct smear and cultured from tissue biopsy specimens or discharge from cutaneous lesions and from pleural fluid, blood, and CSF in systemic infections. Gram-positive bacilli seen on a peripheral smear, in vesicular fluid or CSF are an important finding, and polychrome methylene blue-stained smears showing blue staining bacilli with a capsule visualized in red (McFadyean reaction) provide a presumptive identification. The commercially available QuickELISA Anthrax-PA Kit can be used as a screening test.⁵ Traditional microbiologic methods can provide presumptive identification from cultures. Definitive identification can be obtained through the Laboratory Response Network in each state by methods that include detection of antigen by polymerase chain reaction (PCR), an enzyme immunoassay to detect IgG to protective antigen in paired sera, a matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry assay measuring lethal factor activity in serum samples, and tissue immunochemistry. Specimens suitable for PCR include blood, CSF, pleural fluid, vesicular fluid or eschar material, and tissue biopsy specimens.

The lesion of cutaneous anthrax must be differentiated from ecthyma gangrenosum and from ulcerative skin lesions with regional lymphadenopathy, including rat-bite fever, ulceroglandular tularemia, plague, glanders, scrub typhus, rickettsialpox, cowpox, and orf. Staphylococcal lymphangitis can be distinguished by the discharge of purulent material and by the inflammatory response observed microscopically. Noninfectious causes of eschars include arachnoid bites and vasculitides.²³ The first stage of inhalational anthrax and the clinical features of the intestinal form are nonspecific, so a history of exposure is crucial to establishing the diagnosis. Mediastinal widening of inhalational anthrax can cause confusion with that seen in acute bacterial mediastinitis and in fibrous mediastinitis caused by *Histoplasma capsulatum*.¹⁸ Gastrointestinal anthrax must be differentiated from other causes of acute abdominal illness and, if bleeding is present, from duodenal ulcer, typhoid, and intestinal tularemia. Injection anthrax must be differentiated from other causes of soft tissue infection; the degree of edema, excessive bleeding at time of surgery, and lack of a clear demarcation between affected and healthy tissue are suggestive of injection anthrax.¹ Anthrax meningitis must be differentiated from subarachnoid hemorrhage.

TREATMENT

First-line agents for treatment of naturally occurring uncomplicated cutaneous anthrax include ciprofloxacin or an equivalent fluoroquinolone, or doxycycline. Clindamycin is an alternative, as are penicillins if the isolate is shown susceptible. Treatment for 7 to 10 days is adequate. Treatment of bioterrorism-associated cutaneous disease should be initiated with ciprofloxacin (30 mg/kg per day orally divided every 12 hours, not to exceed 1000 mg every 24 hours), or doxycycline (100 mg

orally 2 times/day for children 8 years of age or older; or 4 mg/kg per day divided every 12 hours, for children younger than 8 years of age with a maximum of 200 mg per day), until susceptibility data are available. The antimicrobial regimen should continue for 60 days to provide postexposure prophylaxis (PEP) and is administered in conjunction with vaccine.⁵

The initial regimen for treatment of all forms of systemic anthrax including cutaneous anthrax with systemic signs should include intravenously administered ciprofloxacin as the primary component of a multidrug regimen (30 mg/kg per day, intravenously, divided every 8 hours, not to exceed 400 mg per dose) until results of susceptibility testing are known. Levofloxacin and moxifloxacin are considered equivalent alternatives to ciprofloxacin. At least two additional antimicrobial agents with CNS penetration, one a bactericidal and the other a protein synthesis-inhibiting agent, should be administered in conjunction with ciprofloxacin until meningitis is excluded. Meropenem is recommended as the second bactericidal agent, with imipenem/cilastatin or doripenem as alternatives; if the strain is known to be susceptible, penicillin G or ampicillin are equivalent alternatives. Linezolid is the suggested protein synthesis inhibiting agent.

If meningitis has been excluded, treatment can consist of two antimicrobials, including a bactericidal and a protein synthesis-inhibiting agent. Clindamycin is preferred as the latter agent, with linezolid, doxycycline, and rifampin as acceptable alternatives. Ciprofloxacin is the preferred bactericidal agent, with meropenem, levofloxacin, imipenem/cilastatin, and vancomycin as alternatives. If susceptible, penicillin G or ampicillin are equivalent alternatives. Therapy should continue for at least 14 days; intravenous can be changed to oral treatment to complete the course as symptoms permit. For bioterrorism-associated anthrax, treatment should be continued for at least 60 days to provide PEP.

For anthrax with evidence of systemic disease, administration of anthrax immune globulin (Anthraxil) or raxibacumab (ABthrax), a humanized monoclonal antibody, should be considered in consultation with the Centers for Disease Control and Prevention (CDC). Anthrax immune globulin can be accessed under a CDC-sponsored investigative new drug (IND) protocol. Raxibacumab is approved by the US Food and Drug Administration.⁵ Supportive therapy includes attention to details of fluid and electrolyte balance, endotracheal intubation if indicated to maintain a patent airway, and local care for cutaneous lesions. Systemic corticosteroids can reduce the severity of infections in patients with massive edema or meningitis.³⁸

PROGNOSIS

Before penicillin was introduced, cutaneous anthrax was fatal in approximately 20% of patients. With effective treatment, the mortality rate is less than 1%. Cutaneous anthrax of the eyelid may be complicated by ectropion of the upper lid and corneal scarring with blindness.⁴³ Immunity probably is lifelong in most patients. Although second attacks of cutaneous anthrax have been recorded, they have not been confirmed serologically and usually are mild.²² Fatality rates are high for systemic anthrax and range from 50% to 100% for gastrointestinal anthrax to virtually 100% for inhalation anthrax, but children who have survived these infections have no apparent sequelae.

PREVENTION AND CONTROL

The only human anthrax vaccine licensed in the United States is anthrax vaccine adsorbed (AVA), marketed as BioThrax, which is prepared from cell-free filtrates of microaerophilic cultures of a toxigenic,

nonencapsulated strain of *B. anthracis* V770-NP1-R. Each 0.5-mL dose contains proteins including the protective antigen and contains no dead or live bacteria. The vaccine is licensed for use in persons 18 to 65 years of age at high risk for exposure. Preexposure vaccination is recommended for persons at risk for repeated exposure to anthrax spores, including some laboratory personnel, persons involved in environmental investigations or remediation efforts, military personnel, and some emergency responders. The preexposure vaccination schedule consists of five intramuscular doses administered at day 0; 4 weeks; and 6, 12, and 18 months, followed by an annual booster to maintain immunity.

The CDC updated its recommendations for exposure to anthrax through bioterrorism and the American Academy of Pediatrics published a pediatric anthrax management document in 2014.^{10,11} In the event of a bioterrorism threat, updates will be posted on the CDC anthrax website (<https://www.cdc.gov/anthrax/bioterrorism/index.html>). Public health authorities will provide a 10-day course of antimicrobial prophylaxis to those likely exposed and will determine those who should continue PEP to complete a 60-day course. Ciprofloxacin (30 mg/kg per day orally divided every 12 hours, not to exceed 1000 mg every 24 hours) and doxycycline (100 mg orally 2 times/day for children 8 years of age or older; or 4 mg/kg per day divided every 12 hours, for children younger than 8 years of age with a maximum of 200 mg per day) are equivalent first-line agents for children; levofloxacin or clindamycin are second-line agents for PEP. If susceptible (minimal inhibitory concentration less than or equal to 0.125 µg/mL), use of amoxicillin (80 mg/kg per day divided into 3 doses with a maximum of 500 mg/dose) may be advised by public health authorities. AVA is not licensed for use in children but will be made available in a bioterrorism event as an investigational vaccine. The process required for use of AVA will be accessible at the CDC website (www.cdc.gov/anthrax) as well as through the American Academy of Pediatrics and the FDA.^{10,11} All exposed children older than 6 weeks of age should receive 3 doses of AVA at 0, 2, and 4 weeks by the subcutaneous route in addition to 60 days of PEP. Infants younger than 6 weeks of age at the time of exposure should begin vaccine when they reach 6 weeks of age.

Worldwide, anthrax is controlled through livestock immunization programs. Procedures to prevent the spread of anthrax in animals include disposal of contaminated carcasses by burning and annual vaccination of livestock in known enzootic areas. Novel approaches to the treatment of anthrax are under investigation and include nonantimicrobial drugs with activity against anthrax toxin components and evaluation of agents that inhibit binding or assembly of toxins.⁶ Suspected or proven cases of anthrax should be reported to public health officials. Hospitalized patients should be kept under isolation until the lesions are bacteriologically sterile. Contaminated dressings and clothing must be burned or sterilized, and the patient's room must be disinfected to destroy spores.

Bacillus cereus is an environmental gram-positive rod that can give rise to two distinct forms of foodborne diseases, the emetic and the diarrheal syndromes, and occasionally to localized and systemic disease.^{57,91} *B. cereus* pathogenicity has been recognized since the early 1950s, with clarification of the taxonomy of the genus *Bacillus*. Multiple early reports of food poisoning and other infections, including gastroenteritis, bacteremia-septicemia, cellulitis, ear and eye infections, endocarditis, and urinary tract infections, which were attributed to *Bacillus subtilis* or to other *Bacillus* spp., probably were caused by *B. cereus*.¹⁴⁵

The diarrheal syndrome was recognized first by Hauge⁶⁵ in 1955 after four clinically similar outbreaks in Norway occurred. This common form of disease was related to a great variety of foods, such as meat and vegetable soup, poultry, pudding, sauce, pasta, cake, and milk. In 1974, Mortimer and McCann¹¹¹ described a vomiting syndrome associated with the consumption of fried rice in Chinese restaurants. Despite widespread recognition in Europe, *B. cereus* outbreaks have been reported infrequently in the United States. The first documented outbreak in the United States occurred in 1970.¹⁰⁸

BACTERIOLOGY

Members of the genus *Bacillus* are aerobic or facultative anaerobic, gram-positive or gram-variable, spore-forming rods. They are distributed widely in the environment because of the high resistance of their endospores to extreme conditions, including heat, cold, desiccation, salinity, and radiation.^{46,132}

Bacillus cereus belongs to the group of gram-positive rods that produce central or terminal ellipsoid or cylindrical spores that do not distend the sporangia.¹⁵¹ Studies of DNA-DNA hybridization and 16S and 23S ribosomal RNA (rRNA) sequencing and enzyme electrophoretic patterns have shown a close relationship among *B. cereus*, *Bacillus anthracis*, *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus weihenstephanensis*, and *Bacillus thuringiensis*; these organisms are so closely related that they all may be considered variants of *B. cereus* and are labeled the *B. cereus* group, or *B. cereus sensu lato*. Based on the high variability in guanine and cytosine content (32% to 69%), the debate ensues regarding the classification of *Bacillus* spp.¹⁵¹ Whole-genome sequencing has shown large amounts of gene transfer between members of the *B. cereus sensu lato*, complicating identification.^{20,99} Pathogenic strains of *B. cereus* are shown to have pathogenic plasmids shared with *B. anthracis* and other species, leading to confusion in clinical and laboratory identification.^{20,99} Differentiating, particularly between *B. cereus* and the insect pathogen *B. thuringiensis*, sometimes is difficult in the diagnostic laboratory, and overlap occurs among clinical syndromes reported.^{64,80} Polymerase chain reaction (PCR) technology, including multiplex-PCR capable of distinguishing members of *Bacillus cereus sensu lato*, pulse field gel electrophoresis, and genomic sequencing, as well as detection of specific emetic and diarrheagenic toxins, have been used for identifying species.^{22,115,93}

B. cereus sensu stricto (i.e., the species *B. cereus* only) is a flagellated, motile, gram-positive rod, typically 1 to 1.2 μm in diameter by 3 to 5 μm in length. The organism sporulates freely on many media under well-aerated conditions, but vegetative cells also can grow anaerobically. It is able to metabolize glucose, fructose, and sucrose, but not pentose and other sugar alcohols. It produces acid from glucose, but not from arabinose, xylose, or mannitol. Starch hydrolysis and catalase production are similar to those of the other members of the genus. The presence of lipid globules or protoplasts is a characteristic that it shares with *Bacillus megaterium*.⁹² Colonies on blood agar are large, flat, granular, and slightly green tinged. *B. cereus* is differentiated from *B. anthracis* by motility, hemolysis, lack of lysis by γ phage, penicillin resistance,

and absence of a capsule in *B. cereus*.⁴⁶ Identifying morphologic differentiation with nonmotile *B. cereus* strains and *B. anthracis* strains that are occasionally weakly hemolytic may be difficult.

Growth and multiplication of vegetative cells occur in a temperature range of 10°C to 50°C (50°F to 122°F), with an optimum of 28°C to 35°C (82.4°F to 95°F). Variations in toxin levels found in certain foods also can be related to pH levels, sugar content, the presence of other lactic acid bacteria, and aeration.^{138,139} Some strains responsible for milk spoilage can grow at temperatures of 5°C (41°F),^{92,132} but few strains are able to produce toxin at temperatures less than 7°C (44.6°F).¹³² Ribosomal DNA characterization and genotyping based on the major cold shock protein homologue *cspA* have defined the species, *Bacillus weihenstephanensis*, which can grow at 4°C to 7°C (39.2°F to 44.6°F) but not at 43°C (109.4°F).⁹⁶ These strains form a subgroup of *B. cereus* organisms described as psychrotolerant or psychrotropic, meaning they are able to grow at temperatures of 7°C (44.6°F) and less.^{95,126,140} Spore formation allows some *B. cereus* strains to survive pasteurization and heating, as well as transit of the acidic conditions of the human gastrointestinal tract to cause diarrheal disease.^{95,28,29} A crystalline cell surface protein layer or “S-layer” has been described as a determinant of cell hydrophobicity. S-layer-producing cells are hydrophilic and able to bind to human matrix proteins, and presence of the S-layer in some *B. cereus* strains is associated with resistance to phagocytosis and increased radiation resistance against γ irradiation.⁹¹

Serologic differentiation of *Bacillus* spp. is hampered by cross-reactive antigens and autoagglutination of spores caused by hydrophobic surface properties. Serologic typing based on the flagellar (H) antigen can be used during an outbreak to distinguish among strains and to determine the similarity of isolates obtained from humans with the strains isolated from suspect foods.⁴⁶ The serotype scheme is based on H antisera raised against prototype strains. In addition to serology, biochemical typing, plasmid analysis, and phage typing have proved useful epidemiologically.^{2,92,114,136,155} A *B. cereus*-specific, repetitive, extragenic, palindromic sequence-based PCR analysis (Bc-Rep-PCR) appears to be a promising newer technique.^{120,129} Pulsed-field gel electrophoresis (PFGE) has been less successful in differentiating among *B. cereus* group species.¹⁶⁶ Developments in genomics, proteomics, and metabolomics have increased ability to distinguish species in *B. cereus sensu lato* for research purposes, but have yet to be used commonly in clinical practice.⁷⁷

Diagnosis of the less common extraintestinal infection is made by isolation from normally sterile sites (blood or tissue) after overnight incubation on nutrient or blood agar; clinical specimens from normally nonsterile sites (feces, vomitus) and food or environmental samples require selective techniques. Polymyxin B is used as a selective agent, and the lecithinase reaction of the organism on egg yolk and its inability to catabolize mannitol permit presumptive identification to be made with a variety of media: mannitol-egg yolk-polymyxin B, Kim and Goepfert medium, and polymyxin B-pyruvate-egg yolk-mannitol with bromothymol blue or bromocresol purple.⁴⁶

EPIDEMIOLOGY

Bacillus cereus in the spore and vegetative form is a ubiquitous organism found in soil, water, vegetation, and food products, especially cereals, dairy products, dried foods, spices, meat products, and vegetables.⁹² The emetic syndrome typically is associated with cooked rice, usually fried, from Chinese restaurants.^{88,111} Saving portions of boiled rice at room temperature overnight until required for frying previously was a common practice. Refrigerating boiled rice makes the grains stick together, which is less convenient for frying. The spores of *B. cereus* survive cooking and are capable of germination and outgrowth.^{58,60} The

optimal temperature for growth in boiled rice is 30°C to 37°C (86°F to 98.6°F), although growth does occur during storage at 15°C to 43°C (59°F to 109.4°F).⁵⁸ Most samples of uncooked rice contain multiple serotypes of *B. cereus*, and little difference occurs in the growth rate of the various serotypes in boiled rice at 22°C (71.6°F).¹¹⁸ In laboratory conditions, using high pressure along with high temperatures for treating cooked rice has been shown to reduce survival of spores, perhaps indicating a method for reduction of clinical disease from contaminated rice dishes.³⁶

Starchy dried foods other than rice, such as cereals, frequently are contaminated.¹⁹ Tortillas can be contaminated with the water used in preparation and from the hands of producers.²⁶ Specific foods incriminated in outbreaks in the United States include Chinese food (accounting for 50% of reported outbreaks between 1973 and 1987), followed by Mexican food, beef, fruits, and vegetables. Other foods implicated, particularly in the enterotoxin syndrome, include beef stew, turkey loaf, barbecued pork, macaroni and cheese, potatoes, spaghetti and other pastas, dairy and dried milk products, and seafoods.^{40,56,70,72,82,91,100}

In a study of 96 milk and milk product samples collected from retail shops in Nairobi, Kenya, 57% of samples were contaminated with *B. cereus* and 81% of the bacterial isolates (38 of 47) produced nonhemolytic enterotoxins, including 6 of 43 pasteurized milk products (43%).¹¹⁷ Infant complimentary foods tested in urban and rural Bangladesh found high levels of diarrheagenic bacteria present, including 6% to 8% of all samples showing growth of *B. cereus*.⁷⁸ In Korea, survey of 687 powdered infant formulas and ready-to-eat-foods from markets found 347 isolates of *B. cereus*, with 95% harboring at least one toxin gene.⁷³ A study of donor breast milk in Spain found that *B. cereus* were the only bacteria to survive the pasteurization process, though they were not genetically virulent strains.³⁹ However, a cluster of two cases of severe *B. cereus* enterocolitis in very-low-birthweight preterm neonates in France found pooled donor breast milk to be the likely source.⁴¹

Among the factors thought to contribute to outbreaks, the most frequent were inadequate cold-holding temperatures, preparing foods a half-day or more before serving, contaminated equipment, and storage in a contaminated environment.^{10,27} Outbreaks of *B. cereus* have been recognized widely in Europe but less often in the United States and Asia. In the Netherlands, *B. cereus* reportedly was the cause of 22.4% of foodborne disease outbreaks of known bacterial cause. Similarly, in Finland, it accounted for 11.9% of outbreaks. In most places, *B. cereus* is incriminated in 0.9% to 7% of outbreaks of food-related disease and 0.7% to 3% of cases.⁹² In Korea, for 36,745 cases of food poisoning referred to the Korea Center for Disease and Prevention between 2007 and 2008, only 129, or 0.35% of cases, were stool culture positive for *B. cereus*, despite concerns that the rate might be higher in a culture with a very rice-dependent diet.¹¹⁶ In the United States, between 1998 and 2002, *B. cereus* was identified as the cause of 37 of 6647 (0.6%) foodborne outbreaks reported to the Centers for Disease Control and Prevention (CDC), with a total of 571 cases and no deaths recorded.¹⁰³ The location of the outbreak is known for 24 of these outbreaks, and most of these (15 of 24 [62.5%]) occurred in commercial food outlets, such as restaurants, delicatessens, or workplace cafeterias. In outbreaks for which the implicated source was known, cereal products were the most common vehicle.¹⁰³ From 1998 to 2008, the CDC reported 56 confirmed and 179 suspected foodborne outbreaks of *B. cereus* with a total of 2050 cases resulting in 0 deaths. Fifty percent of confirmed outbreaks involved rice dishes as the implicated source, and 67% of confirmed outbreaks were associated with foods prepared in a restaurant or deli.¹⁷ The susceptibility of children to this pathogen is evident from the report of an outbreak involving two daycare centers⁸⁸ and other reports that included neonates, children, and adolescents.^{42,49,67,81,113,119,131,146,161} Only a small fraction of outbreaks are reported to the CDC; small outbreaks of mild, brief illness are less likely to be reported. It is thought that 10⁵ to 10⁸ organisms per gram need to be ingested to cause the emetic syndrome and 10⁵ to 10⁷ cells or spores (total dose) ingested to cause the enterotoxin syndrome.⁶¹

For infections not related to food, groups at risk include neonates,^{49,119,133} immunocompromised hosts,^{4,30,48,60,67,81,87,136,143} patients with recent eye surgery or trauma, intravenous drug users,^{33,146} and patients with intravascular devices or artificial prostheses.^{6,8,48,49,136,137} *B. cereus*

has been known to contaminate a variety of unusual environmental niches, including alcohol prep pads,⁴⁵ steam-dried towels,⁴⁴ hospital linens during a period of hospital construction,⁵ and unopened boxes of nonsterile nitrile gloves.⁸⁴ Studies in three populations in South Africa and London, including school-aged children, found the organism in 18% to 43% of fecal samples.¹⁵⁰ The organism can be part of the normal intestinal flora. *B. cereus* does not persist in the intestine after ingestion and so is not spread by the fecal-oral route.⁵⁵

PATHOGENESIS

Bacillus cereus produces an enormous range of extracellular metabolites, including peptides with antibiotic properties (biocerin, cerein, thiocillins), β -lactamases, hydrolases, nuclease, urease, and proteases.¹⁴⁵ Two groups of toxins, known as diarrheal enterotoxins and emetic toxins, are responsible for the clinical syndromes of food poisoning.^{106,148} There is great variability of toxicity and clinical spectrum of illness among *B. cereus* isolates.⁸⁶ Some strains may be able to produce both toxins based on the evidence that culture filtrates derived from strains isolated from emetic poisoning occasionally are able to produce a positive rabbit ileal loop assay.¹³²

Biologic activities of diarrheal enterotoxins can be shown in multiple different assay systems. Three enterotoxins, nonhemolytic enterotoxin (Nhe), hemolysin BL (Hbl), and cytotoxin K (CytK), are produced and regulated by multifactorial, complex processes.⁸³ Purification plus isolation of multiple toxic fractions with some, but not all, of these activities has caused confusion.^{46,144} Evaluation of the toxic activity of whole-cell suspension, cell-free culture filtrates, and the purified enterotoxin complex classically has included the rabbit ileal loop fluid accumulation assay, vascular permeability in rabbit skin, dermonecrosis and intestinal necrosis, mouse lethality, cytotoxicity, and hemolysis.^{15,24,98,141,147,152} Hemolytic *B. cereus* enterotoxin has been characterized as a complex termed *hemolysin BL*, composed of a binding component B (35 kDa) and two lytic components, L1 and L2 (36 kDa and 45 kDa, respectively)¹¹; all three are needed for fluid accumulation in the rabbit ileal loop.¹³ Other *B. cereus* enterotoxins, a nonhemolytic enterotoxin and cytotoxin K, also have been described.^{21,91,102} These toxins also damage lung epithelial cells in cases of *B. anthracis*-like pneumonia, with varying levels of cytotoxicity depending on the level of aeration.⁸⁹

The emetic toxin cereulide, encoded in a megaplasmid and produced by a large enzyme complex known as the Ces-non-ribosomal cereulide peptide synthetase, is well characterized.⁵¹ It is a heat-stable (126°C [258.8°F] for 90 minutes), ring-shaped peptide with a molecular weight of 1.2 kDa¹⁰⁷; it is stable between pH 2.0 and 11.0 and is protease-resistant. Cereulide variants with differing cytotoxicity have been found among different isolates of *B. cereus*, likely contributing to the spectrum of clinical illness possible with the emetic syndrome.¹⁰⁵ In contrast to the diarrheal toxins, it is preformed in foods, so the presence of living organisms at the time of ingestion is not necessary to cause symptoms.^{57,145} Rice culture filtrates derived from emetic syndrome-associated strains cause cytoplasmic vacuolation and swollen mitochondria in Hep-2 cells, characteristics suggestive of uncoupling of oxidative phosphorylation.¹²⁷ Emetic activity occurs through the serotonin 5-HT₃ receptor and stimulation of the vagus afferent nerve.¹

Among the multiple other substances with relevant activity, two groups are associated with local infection.^{147,149} Cereolysin, or hemolysin I, is a thiol-activated cytolysin. Phospholipase C-like or lecithinase-like substances, including a sphingomyelinase and two hydrolases with preference for phosphatidylcholine and phosphatidylinositol, also exist. These enzymes induce the release of lysosomal enzymes from neutrophils that probably are involved in tissue damage, especially in wound and ocular infections.^{46,163}

CLINICAL MANIFESTATIONS

Food Poisoning

Diarrheal Syndrome

The enterotoxins preformed in food or produced in vivo in the intestine after the ingestion of bacilli cause profuse, watery, nonbloody diarrhea accompanied by abdominal pain and cramps, nausea, and, occasionally, vomiting or low-grade fever.^{44,56,82,92,101,135} The typical incubation period

is 8 to 16 hours, and the clinical characteristics resemble the food poisoning of *Clostridium perfringens*. The interval between ingestion and the onset of symptoms reflects the time required for production of toxin in the gut. The symptoms resolve within approximately 12 to 24 hours but occasionally can last 2 days to 2 weeks.⁵⁶ The diarrhea (three to ten bowel movements per day) rarely leads to dehydration in healthy individuals. The most prevalent flagellar H serotypes are 1, 2, 6, 8, 10, 12, and 19. Serotyping is available at research laboratories.^{19,40,100,150}

Emetic Syndrome

The usual illness is characterized by a rapid onset (within 1 to 5 hours after the ingestion of contaminated food) of nausea, vomiting, and malaise, occasionally followed by diarrhea hours later.¹¹¹ Infrequently, the diarrhea is reported to last several days.¹⁵⁷ The short incubation reflects the ingestion of preformed emetic toxin.

Extraintestinal Infections

Eye Infection

Keratitis, conjunctivitis, endophthalmitis, and panophthalmitis can be produced by *B. cereus*. Endophthalmitis that develops after the occurrence of penetrating wounds is caused by this organism in 27% to 46% of cases.^{37,154} A history of soil contamination or the presence of a metal foreign body should raise clinical suspicion. Less frequently, corneal ulcers and surgical procedures are predisposing factors.^{66,154,9,123} Exogenous endophthalmitis usually progresses rapidly, with deterioration of vision occurring in less than 48 hours. Severe pain is accompanied by chemosis, periorbital swelling, proptosis, and pus in the anterior chamber. The classic lesion is a corneal ring abscess, similar to that produced by *Pseudomonas* and *Proteus* spp. Endogenous cases may have subretinal exudation, retinal hemorrhage, and perivasculitis. Associated systemic symptoms are not unusual manifestations.³³ CT imaging may show posterior dislocation of the lens, hyperdense vitreous humor, and increased density of retroorbital soft tissue.⁹⁴ The outcome is poor, with almost half of patients left with visual acuity no better than simple light perception.¹⁵⁴ Clinical severity was shown to be associated with *vrr* genotype in a series of 24 cases of *B. cereus* endophthalmitis in China.⁷¹ Many patients require enucleation. Endogenous ophthalmitis is associated with the use of illicit intravenous drugs or transfusion of contaminated blood products and subsequent bacteremic seeding of one eye.^{33,136,143,154}

The pathogenesis of *B. cereus* on ocular tissue has been linked to the lecithinase activity of phospholipase C. A toxin fraction, hemolysin BL, which is formed by three separate components, produces similar destruction of retinal tissue in vitro and in animal experiments.¹² Its relationship with the diarrheal enterotoxin is unclear.¹⁵

Wound and Soft Tissue Infections

Wound infections of variable severity related to trauma, burns, or postsurgical complications occasionally are reported.^{149,146,147,161} Because *Bacillus* is a common environmental contaminant, proof of the relevance of a *B. cereus* isolate is clearer if the organism is obtained from deep tissue in heavy pure growth. Severe infections in individuals involved in motor vehicle accidents can be complicated by necrotizing fasciitis and require extensive debridement.¹⁶¹ Superficial, benignly infected wounds are common findings in the tropics.⁴⁷ Immunosuppressed patients may contract a severe gas gangrene-like infection with myonecrosis similar to disease caused by *Clostridium* spp.,^{107,125} requiring amputation,⁶³ or a less severe primary cutaneous infection manifested by vesicles, pustules, or cellulitis.⁶⁷

Skeletal Infections

Cases of chronic osteomyelitis occur rarely and result from accidental or surgical trauma. Radical debridement and antibiotic treatment are required.¹³⁶ Because *B. cereus* can be found as a copathogen with other, more frequent pathogenic bacteria, resolution of symptoms is delayed until eradication of the organism.¹³⁴ Acute osteomyelitis may occur in drug users.^{136,143}

Bacteremia and Septicemia

Bacteremia occurs with indwelling catheters and other foreign bodies, contaminated intravenous drugs (e.g., heroin), and blood products,

particularly platelets.^{23,48,164,75,158} Immunosuppression and impaired neutrophil killing, such as occur in individuals with neutropenia secondary to malignancy or chemotherapy and in neonates with immaturity of the immune system, are major contributors to morbidity in systemic *B. cereus* infection.^{6,24,68,74,76,119,122,153} Disseminated intravascular coagulation, multiorgan failure, and a fulminant course may occur in neonates and compromised hosts. Intestinal perforation with abdominal infection in neonates also has been described.⁵⁹ Outbreaks of sepsis in newborn nurseries have been linked to contaminated ventilation balloon devices.¹⁵⁶ Endocarditis is an infrequent complication of bacteremia that usually occurs in intravenous drug users or individuals with a long-term intravascular device.^{112,136,143} Vegetations can form over mechanical prosthetic valves or pacemaker wires, requiring their replacement.^{136,137} Morbidity and mortality rates are high in patients with valvular heart disease. Fatal serosanguineous pericarditis in a patient undergoing hemodialysis has been reported.⁵²

Pneumonia

Primary pulmonary disease rarely has been recorded. Underlying predisposing conditions include leukemia, alcohol abuse, chronic hepatitis, and steroid use.^{16,48,74,136} Multiorgan disease in premature neonates with necrotizing pneumonia usually is fatal.⁸⁵ Outbreaks of *B. cereus* pneumonia in neonates have been linked to contaminated ventilators.⁶² Blood culture is positive in 75% of cases, followed by pleural fluid and sputum culture in 40% to 60%.¹⁶ The pleural space may become contaminated with *B. cereus* by mishandling of the thoracic drainage system in patients with other causes of pleuritis.⁷⁹

A dramatic pulmonary syndrome similar to that of inhalational anthrax has been seen in adults (all metal workers) with *B. cereus* infection. The organisms in these cases possessed some *B. anthracis* toxin genes while being clearly phenotypically *B. cereus*.^{3,69,70}

Infection of the Central Nervous System

Premature neonates are susceptible to meningeal seeding by dissemination of intravascular infection related to catheters.¹¹⁹ As in patients with other serious infections, patients who are immunosuppressed are at higher risk.⁷⁴ The cerebrospinal fluid in *B. cereus* meningitis is purulent, with white blood cell counts of more than 1000/mm³, a predominance of polymorphonuclear leukocytes, and moderate increments in protein content. Gram stain is positive in 70% of cases. Multiple brain abscesses may result from hematogenous spread in patients with leukemia.^{74,81,121,35,159} Sequelae include hydrocephalus and brain damage. Often, these infections are fatal.

Intracranial shunts and penetrating surgical or traumatic cranial wounds expose the central nervous system to environmental *B. cereus*.^{49,134} Spinal anesthesia⁴⁸ was associated with *Bacillus* infection in the past. Contamination in the operating room through the linen is a potential source.^{7,8} These infections are typically more benign.

Liver Failure

Fulminant hepatitis and rhabdomyolysis have been associated with the emetic toxin. The toxin inhibits hepatic mitochondrial fatty acid oxidation. Liver changes include fatty infiltrates and midzonal necrosis.¹⁰⁴ This has been implicated in sudden death within hours of onset in cases of *B. cereus* emetic syndromes^{43,105} and has been treated in at least one reported case with emergent liver transplant in a young child,¹⁴² though in other cases the liver failure has been reversible.¹²⁸ Most reported cases are in children and adolescents.

Pseudoinfections

Pseudoepidemics with *B. cereus* are a challenge for the clinical microbiologist.¹⁰⁹ Because these spore formers are so hardy, they are common laboratory contaminants. *Bacillus* spp. isolated from a single clinical specimen usually should be considered a contaminant, although their pathogenic potential is well known.^{34,48,76,122,136,143,147,149} Pseudoinfections have been associated with contaminated blood culture media, syringes, blood culture analyzers, and fiberoptic bronchoscopes.³⁴ Colonization of umbilical cord stumps and eye surfaces by contaminated linens may cause pseudo-outbreaks in nurseries.¹⁶²

COMPLICATIONS

Death rarely ever results from the food-poisoning syndromes. Rapidly spreading wound infections may require amputation of extremities,⁶⁰ and ocular infections can lead to loss of vision with or without enucleation.^{66,154,163} The risk for death in patients with septicemia, endocarditis, and meningitis, as well as fulminant liver failure, is related to the underlying condition and severity of the disease.^{6,67,110,119,137}

DIAGNOSIS

The laboratory finding of *B. cereus* in a foodstuff without quantitative cultures and without epidemiologic data is insufficient to establish its role in an outbreak.¹⁵⁷ In practice, appropriate specimens often either are unavailable or are submitted long after the incident, rendering their microbiologic significance questionable. During analysis of foods not involved in foodborne illness, the bacteria may be found in counts of 10^1 to 10^6 organisms per gram.^{18,19,26,58,118,138} Emerging advances in diagnostics including multiplex PCR for identification of toxin-encoding genes,¹⁶⁵ real-time PCR for detection of spores in contaminated foods,⁵⁰ transcriptionomics, and genomics^{77,130} will allow for more rapid and specific identification and classification of strains of *B. cereus* found in incriminated foods, as well as from patient samples in outbreak investigations. Diagnosis of the diarrheal form of *B. cereus* food poisoning is supported by the isolation of 10^5 or more organisms per gram from epidemiologically incriminated food.¹¹⁰ The levels of *B. cereus* found in the implicated foods usually are in the range of 5×10^5 to 9.5×10^8 colony-forming units per gram. With the exception of milk, the products rarely appear to be spoiled, despite the bacteria's high density. Isolation of more than 10^5 organisms per gram in feces during an acute attack provides supportive evidence for the presumed diagnosis and confirms the association if the same serotype is isolated from incriminated food.

The organisms that produce emetic toxin are present in concentrations of 1×10^3 to 5×10^{10} colony-forming units per gram. Reheating may decrease or eliminate the organisms and leave the toxin intact, but render isolation of the organism difficult to accomplish.^{46,157} Accurate PCR assays for the presence of the emetic toxin-producing *B. cereus*, as well as liquid chromatography-tandem mass spectrometry for quantification of cereulide toxin, have been developed and can be performed on food samples.^{53,90,124}

Commercial immunoassay kits (reversed passive latex agglutination test, enzyme-linked immunosorbent assay, and microslide immunodiffusion assay) are available for the detection of *B. cereus* diarrheal toxin. The kits may detect a variety of proteins, however.^{12,14,38} Experimental techniques based on the detection of genes for phospholipase C and sphingomyelinase by PCR have been developed for the identification of *B. cereus* in food products.¹⁰⁷

The relevance of clinical isolates in extraintestinal syndromes can be assessed by the degree of growth (heavy vs. scanty), the number of occasions that growth was obtained, the source of the material cultured, and predisposing or underlying conditions.¹⁴⁹ For suspected endophthalmitis, aqueous and vitreous samples should be obtained.³⁷

TREATMENT

During a mild, self-limited attack of food poisoning, patients require only supportive therapy. Usually, oral fluid and electrolyte replacement is adequate (Table 92.1).⁵⁶

No antibiotic therapy is required except in cases of nongastrointestinal infection. The production of three β -lactamases by most of the organisms renders penicillin derivatives, including third-generation cephalosporins, ineffective against *B. cereus*. Most strains are susceptible to chloramphenicol, vancomycin, clindamycin, aminoglycosides, erythromycin, tetracycline, imipenem, and ciprofloxacin.^{6,31,147,149,160} Definitive antibiotic therapy should be based on the antibiogram susceptibility, but initial empirical therapy with clindamycin or vancomycin, with or without an aminoglycoside, is appropriate, pending susceptibility data.^{6,16,34,81,131,161} Ciprofloxacin has also been reported to be useful in the treatment of recurrent pneumonia and bacteremia⁵⁴ and may have advantages in the penetration of respiratory and eye secretions.⁹⁷ Immediate empirical coverage for *B. cereus* is indicated

TABLE 92.1 Management and Complications Associated With *Bacillus Cereus* Infections

Condition	Management	Complications
Food poisoning	Supportive measures; hydration	Usually none; liver failure and sudden death rarely reported
Ocular	Systemic, topical, intravitreal antibiotics: vancomycin and/or ciprofloxacin; surgical—early vitrectomy ³¹	Severe decreased visual acuity, blindness, enucleation
Septicemia	Removal of IV device, foreign body; IV antibiotics (according to sensitivity): vancomycin	Localization of infection: endophthalmitis, endocarditis, meningitis; death
Pneumonia/pleuritis	IV antibiotics; drainage of pleural space; resection of necrotic tissue	Death
Meningitis	IV antibiotics; removal of infected intracranial shunts or cerebrospinal fluid reservoirs	Hydrocephalus, brain damage, death
Wound/subcutaneous infection	IV antibiotics; surgical debridement	Amputation, death

IV, Intravenous.

for endophthalmitis in groups at risk. Vancomycin and ciprofloxacin administered intravitreally are the best options.²⁵ In cases of penetrating trauma, early vitrectomy should be considered.^{37,154}

Surgical debridement of necrotic tissue, drainage of closed-space infections, and prompt removal of foreign bodies and indwelling catheters are important aspects of successful therapy.^{16,32,131} Some bacteremic patients may be cured by removal of the intravenous catheter only.¹³⁶

PREVENTION AND CONTROL

Low-level contamination in food products is difficult to avoid, but proper food handling should diminish the proliferation of bacilli.¹³² Practical precautions for handling cereals and rice include not preparing large quantities at a single time and maintaining the food at a hot temperature ($>63^\circ\text{C}$ [96.8°F]) or cooling it quickly. The food must not be stored under warm conditions, especially in the range of 15°C to 50°C (59°F to 122°F).^{19,58}

Arcanobacterium haemolyticum

Natascha Ching

Arcanobacterium haemolyticum is a pleomorphic gram-positive coryneform rod that causes pharyngitis and exanthem in children and young adults.^{19,42,46,51}

HISTORY

This diphtheroid was first noted by MacLean and colleagues⁴⁶ in association with exudative pharyngitis in American servicemen in the South Pacific during World War II. The organism was originally named *Corynebacterium haemolyticum*, but was reclassified in 1986 as *A. haemolyticum* on the basis of phenetic, peptidoglycan, fatty acid,

menaquinone, and DNA data.^{17–19} The association between infection with *A. haemolyticum* and pharyngitis was observed repeatedly over the years, but a cause-and-effect relationship between the organism and illness has been established only relatively recently.^{11,46,51}

ORGANISM**Microbiology**^{19,21,27,78,81}

A. haemolyticum is a gram-positive to gram-variable pleomorphic rod. Its laboratory characteristics are presented in Table 93.1. The organism

TABLE 93.1 Identification Characteristics of *Arcanobacterium haemolyticum*^a

Test or Characteristic	Finding
Catalase	Negative
β-Hemolysis	Positive (a narrow zone of slight hemolysis after 48 hr on sheep blood)
Nitrate reduction	Negative
Pigment production	White or gray
Urease	Negative
Gelatin hydrolysis	Negative
Motility	Negative
Esculin hydrolysis	Negative
Carbohydrate use:	
Glucose	Positive
Maltose	Positive
Sucrose	Positive (requires rabbit serum for growth in peptone water)
Mannitol	Negative
Xylose	Negative

^aData from Collins MD, Cummins CS. Genus *Corynebacterium*. In: Sneath PHA, Main NS, Sharpe ME, et al, editors. *Bergey's manual of systemic bacteriology*. Vol. 2. Baltimore, MD: Williams & Wilkins; 1986:266-276.

grows best at 37°C (98.6°F) on a blood- or serum-enriched medium with the addition of 5% carbon dioxide. Alternatively, it grows well anaerobically. On rabbit or human blood agar, colonies are pinpoint (0.5 mm) at 24 hours; they increase to 1 to 1.5 mm after 48 hours. At this time, a unique black opaque dot is noted in the center of the colony, and this dot remains on the agar when the colony is scraped away.

At 24 hours, a 1-mm zone of hemolysis develops around colonies grown on human or rabbit blood agar. The hemolytic zone increases to 3 to 5 mm by 48 hours. Both growth and red cell hemolysis are minimal on horse and sheep blood agar. Because throat cultures usually are performed on sheep blood agar plates, the hemolytic activity of *A. haemolyticum* may be missed.

Colonies of *A. haemolyticum* can be of either the smooth or rough biotypes on horse blood agar.¹³ These biotypes also differ in their hemolysis and biochemical properties. Smooth colonies predominate in wound infections and frequently use sucrose and trehalose, are β-hemolytic, and lack β-glucuronidase. Rough colonies are found almost exclusively in the respiratory tract and do not use sucrose and trehalose, are nonhemolytic, and are β-glucuronidase positive.

A. haemolyticum resembles *Actinomyces pyogenes* (formerly *Corynebacterium pyogenes*), a common cause of bovine mastitis and a rare cause of skin ulcers in children.³⁸ These organisms can be differentiated by several means. *A. pyogenes* is able to hydrolyze gelatin and to ferment xylose. In addition, *A. haemolyticum* has a positive reverse Christie, Atkins, and Munch-Petersen (CAMP) test in that it inhibits the β-hemolysis of *Staphylococcus aureus*, whereas *A. pyogenes* shows slight enhancement of β-hemolysis.²⁶ The poor growth of *A. haemolyticum* on tellurite medium and lack of catalase help to distinguish it from *Corynebacterium diphtheriae*, which also causes pharyngitis.^{32,39,42}

Toxin Production

A. haemolyticum liberates three toxins: phospholipase D (PLD), a hemolysin, and neuraminidase.¹⁹ PLD is a dermonecrotic toxin that, after intradermal inoculation in rabbits and guinea pigs, causes local hemorrhagic necrosis; injection of PLD also is lethal in rabbits.⁶¹ The PLD gene of *A. haemolyticum* has a high degree of homology to that of *Corynebacterium pseudotuberculosis*.^{20,49} PLD has been shown to be involved in the virulence of *C. pseudotuberculosis*; PLD mutants are less pathogenic in experimental infections in goats.⁴⁸ The PLD of *C. pseudotuberculosis* is similar biochemically and shares some biologic activity with the PLD that is found in brown recluse spider venom where it plays a role in the venom's toxicity.^{6,42} *A. haemolyticum* carries a gene similar to the gene encoding the erythrogenic toxin of *Streptococcus pyogenes*.¹⁹

Antimicrobial Susceptibility

Almost all *A. haemolyticum* strains are highly susceptible to erythromycin (minimal inhibitory concentration <0.06 µg/mL). However, erythromycin is not bactericidal.^{10,46,78} Carlson and colleagues¹² reported an *A. haemolyticum* isolate from a diabetic foot ulcer that was exceptionally resistant to macrolides, clindamycin, tetracycline, and ofloxacin. Waagner⁷⁸ noted that of 100 pharyngeal isolates, all were inhibited by concentrations of 0.25 µg/mL or less of penicillin G and by 1 µg/mL of penicillin V. However, tolerance to penicillin has been observed.^{46,58} In one study, the minimal bactericidal concentration/minimal inhibitory concentration ratio varied from 1:1 to 1:8.⁴⁶ In addition to being susceptible to penicillin and erythromycin, *A. haemolyticum* also is susceptible to other β-lactams, clindamycin, chloramphenicol, azithromycin, vancomycin, ciprofloxacin, tetracyclines, and rifampin; most strains are resistant to sulfonamides and trimethoprim-sulfamethoxazole.^{10,12,78}

Carlson⁹ compared the E test and agar dilution methods for susceptibility testing of 12 antimicrobial agents in 70 *A. haemolyticum* isolates. E test and agar dilution method results for benzylpenicillin, clindamycin, erythromycin, imipenem, levofloxacin, rifampin, and vancomycin were in 100% agreement. Tetracycline, ciprofloxacin, and ofloxacin were in agreement between 97% and 99% of the time, but a lower percentage of agreement was found for cefotaxime and cefuroxime, at 93% and 84%, respectively. The author reinforces the concept that, because there are no universal standards for the organism in regard to susceptible, intermediate, or resistant categories, results should be interpreted with caution for clinical care. Almuzara and associates¹ also evaluated the susceptibility of 19 strains of *A. haemolyticum* according to National Committee for Clinical and Laboratory Standards (now the Clinical and Laboratory Standards Institute [CLSI]) interpretative standards for aerobic organisms. The majority of isolates were susceptible to penicillin, cephalosporins, clindamycin, ciprofloxacin, vancomycin, and macrolides (erythromycin and azithromycin). However, only 68% of isolates were found to be sensitive to tetracycline.

Recommendations for antimicrobial susceptibility testing of *Arcanobacterium* are provided in the CLSI document M45 entitled "Methods for Antimicrobial Dilution and Disk Susceptibility Testing of Infrequently Isolated or Fastidious Bacteria." Table 5 in this document is for *Corynebacterium* spp. and coryneforms and also applies to *Arcanobacterium* spp. The recommended MIC method for testing *Arcanobacterium* spp. uses broth microdilution with cation-adjusted Mueller-Hinton broth (CAMHB) supplemented with 2.5% to 5% lysed horse blood (CAMHB-LHB); there is currently no disk diffusion method recommended.¹⁶ This method involves testing in cation-adjusted Mueller-Hinton broth supplemented with lysed horse blood (2.5% to 5% v/v). Some investigators have used agar dilution or E test satisfactorily.⁹

A vancomycin-resistant *A. haemolyticum* isolated from stool during an outbreak of vancomycin-resistant enterococci has been described. It contained the *vanA* gene primarily found in *Enterococcus faecium*.⁶² Two other case reports have described organisms resistant to ciprofloxacin⁷⁶ and tetracycline.⁴¹

Miyamoto et al. reported seven elderly patients with skin and soft tissue infections with *A. haemolyticum* that were susceptible to minocycline, vancomycin, and β-lactam antibiotics, but resistant to gentamicin and levofloxacin.⁵³

EPIDEMIOLOGY

Although similar organisms are common causes of infection in animals, humans appear to be the primary host of *A. haemolyticum*.^{66,78} The organism is isolated primarily from throat specimens in patients with pharyngitis,^{46,51,78} although it also may be a commensal of human skin.⁴⁵ It likewise may be a commensal in the throat but often is overlooked because laboratories frequently do not differentiate diphtheroids, which are considered "normal flora." In addition, because *A. haemolyticum* often is found in polymicrobial respiratory tract infections with classic respiratory pathogens, including *S. pyogenes*, it sometimes is missed when these more classic pathogens are identified.⁴²

Although no definitive data are available, spread from person to person is assumed to be from the throat discharge of an infected person

to the throat of a susceptible host. Transmission could occur directly or indirectly by fomites. Secondary cases in families indicate that spread is from person to person rather than from an environmental source.^{24,51}

In an 8-year study, the organism was isolated from throat specimens in each year, with isolation rates varying from 0.2% to 0.7%.⁵¹ The peak age for contracting illness caused by *A. haemolyticum* is during the second decade of life; in contrast, the peak age for developing pharyngitis caused by *S. pyogenes* is during the first decade of life.^{24,46,51} In two studies, illnesses occurred more commonly in females than in males.^{24,51} In a review of *A. haemolyticum* systemic and deep-seated infections, a preponderance of males over females was found in adolescents, with no risk factors for development of invasive disease.⁷¹ No seasonal prevalence has been reported.

Screening throat cultures for pharyngotonsillitis in northern Israel was performed in 518 throat cultures in patients aged 1 to 90 years.¹⁵ Only one culture was positive (0.2%) for *A. haemolyticum* in contrast to 26% recovery of group A *Streptococcus*. However, the one case was in a 9-year-old patient and only 58.7% of patients were 1 to 18 years old, the more common age of isolation for this organism.

PATHOGENESIS AND PATHOLOGY

Few data are available regarding pathogenesis and pathology. The dermonecrotic toxin probably plays a role in pharyngitis. Skin biopsy specimens taken from the exanthem in two patients both showed only a mild lymphohistiocytic perivascular infiltrate.⁵¹ Cultures of both samples were negative, and no IgG, IgA, or IgM deposition was noted. These findings suggest that the rash may be toxin mediated, similar to the rash in group A streptococcal infections.

A. haemolyticum persists intracellularly,⁵⁹ which might account for failure of penicillin treatment in some cases.

In one study, five of 42 patients were found to have apparent dual infections with Epstein-Barr virus and *A. haemolyticum*.⁴⁶ The authors of this study suggested that immune suppression by the virus contributes to a more marked effect of the bacterial infection in the throat.

With regard to the immune response to *A. haemolyticum*, paired acute and convalescent sera showed the development of a humoral response to four distinct cell wall-associated proteins on Western blot analysis in seven of eight patients with culture-confirmed infection.⁵⁶

CLINICAL MANIFESTATIONS

Pharyngitis

Pharyngitis is the most common finding in *A. haemolyticum* infection.* Signs and symptoms associated with pharyngitis are presented in Table 93.2. The illness is indistinguishable from that caused by group A streptococci; frequently it resembles Epstein-Barr virus infectious mononucleosis. Several patients with typical infectious mononucleosis had laboratory evidence of infection with both Epstein-Barr virus and *A. haemolyticum*.^{29,30,46} Peritonsillar abscess caused by *A. haemolyticum* has been reported on several occasions.^{4,39,43,52} The most common exanthem is scarlatiniform, which has an onset 1 to 4 days after the beginning of pharyngeal symptoms. The rash is most prominent on the extensor surfaces of the arms and legs (Fig. 93.1). Circumoral pallor, which is seen with group A streptococcal scarlet fever, does not seem to occur with *A. haemolyticum* infection. The rash may progress to involve the chest and back; it usually spares the palms, soles, and face, and it rarely involves the abdomen and buttocks.

The rash frequently is pruritic and may be urticarial. Erythema multiforme has been described.³ Gaston and Zurowski²⁸ reported a 20-year-old man who had, in addition to pharyngitis, a rash involving mainly his hands and feet. His feet were swollen, and erythematous macules, petechiae, and vesicles were on the soles. His palms were tender, and 2- to 4-mm erythematous macular lesions that contained small central vesicles were present. Recently, Mehta⁵⁰ reported a 19-year-old woman who presented with pharyngitis and a pruritic rash on her arms and legs 4 days before evaluation. Physical examination revealed an erythematous, urticarial rash with large and small annular rings over

TABLE 93.2 Signs and Symptoms in Children, Adolescents, and Young Adults With *Arcanobacterium haemolyticum* Infection

	Frequency (%)
Symptoms	
Sore throat	100
Rash	40–70
Pruritus	50
Fever	40–75
Hoarseness	60

Vomiting	30
Signs	
Pharyngitis or tonsillitis	100
Exudative	50–70
Palatal petechiae	30
Glossitis	25
Cervical lymphadenitis	40–75
Rash	40–70
Scarlatiniform	50
Urticarial	5
Maculopapular	25

Data from references 24, 33, 43, 48, 71.

FIG. 93.1 An erythematous maculopapular discrete and confluent rash on the thigh and arm of a 16-year-old girl with pharyngitis and *Arcanobacterium haemolyticum* isolated from her throat. (From Mackenzie A, Fuite LA, Chan FTH, et al. Incidence and pathogenicity of *Arcanobacterium haemolyticum* during a 2-year study in Ottawa. *Clin Infect Dis*. 1995;21: 177–1781.)

the whole body with confluence on the upper thighs, and smaller lesions groups on distal dorsal parts of the hands and feet.

Carlson and associates¹⁴ also reported a 19-year-old man who presented with a 2-day history of a pruritic exanthem on the upper back and chest that spread centrifugally. The patient had pharyngitis that worsened to exudative tonsillitis, and a throat culture was positive for *A. haemolyticum*. He also had swollen fingers and worsening erythematous maculopapular exanthem over his trunk and proximal extremities. Interestingly, Pastia's lines were observed on the third day. Two weeks after antimicrobial treatment and discharge, a mild late desquamation was noted on the palms and around fingernails.

The duration of the exanthem has not been described adequately in the literature. In one study, exanthem was noted to persist for longer than 2 days in 69% of patients.⁴⁸

On occasion, *A. haemolyticum* infection has been manifested as a grayish-white pharyngeal pseudomembrane that has been confused

*References 3, 11, 24, 28, 30, 32, 36, 45, 46, 51, 55, 57, 67, 68, 70, 77, 78.

with diphtheria.^{3,32,35,39} *C. diphtheriae* and *A. haemolyticum* are diphtheroids that cannot be distinguished on Gram stain but can be differentiated by their biochemical properties.

Skin Infections

In the initial report of infections with *A. haemolyticum* in 1946, MacLean and associates⁴⁶ noted both pharyngitis in US servicemen and skin infections in the native populations of the South Pacific Islands. Cutaneous infections have been observed mainly in tropical countries.⁷⁸ The most common manifestations are ulcerative lesions that resemble ecthyma. Cellulitis, wound infections, and paronychia all have been noted.* In wound infections, mixed infections with *A. haemolyticum* and other organisms are common findings.

Tan and colleagues⁷⁴ report five cases of *A. haemolyticum* bacteremia associated with soft tissue infections in adults. These patients had a history of soft tissue infections; two elderly bedridden patients had decubitus ulcers, and three diabetic patients had foot ulcers with extensive involvement that required surgical debridement. Four patients also had *A. haemolyticum* isolated from the suspected soft tissue focus of infection. A 3-year retrospective review of clinical samples over the same period as the five reported cases revealed 25 isolates of *A. haemolyticum*. Isolates from wound infections or cellulitis were found in 96% of cases; 20% of those patients also had bacteremia. Cultures from nonsterile sites were often polymicrobial, but the authors report *A. haemolyticum* was usually the predominant isolate.

Malini and colleagues⁴⁷ report three individuals with soft tissue infections with mixed infections with *A. haemolyticum* and β -hemolytic streptococci group G in a patient with cellulitis, β -hemolytic streptococci group A in postoperative wound infection, and *Proteus vulgaris* in a diabetic patient with chronic osteomyelitis. Each of these patients responded to erythromycin alone or in combination with penicillin or ciprofloxacin therapy. *A. haemolyticum* may have a synergistic role in tissue damage in these mixed soft tissue infections.

Sinusitis/Orbital Cellulitis

Individual cases have been reported in healthy children and young adult patients diagnosed with sinusitis and complications of orbital cellulitis. The cases seem to have acute refractory orbital cellulitis, possibly preceded by pharyngitis, sinusitis, or history of rash. These cases have similar clinical histories with an aggressive clinical course requiring repeat surgical drainage and debridement.

Limjoco-Antonio and colleagues⁴¹ report a 9-year-old girl with a swollen right eye after blunt trauma. She had ethmoid and maxillary sinusitis and orbital cellulitis, which required surgical drainage, debridement of subperiosteal abscess, and a second procedure with external ethmoidectomy and endoscopic sinus surgery. Cultures from the ethmoid sinus grew *A. haemolyticum*, and she was treated with ceftriaxone and clindamycin.

Stone and Harshbarger report a rare case of ethmoid sinusitis that progressed to orbital necrotizing fasciitis and osteomyelitis due to *A. haemolyticum* in a 16-year-old male.⁷³ He initially presented with concerns of periorbital cellulitis and sinusitis but progressed on intravenous vancomycin, clindamycin, and ampicillin-sulbactam. He had soft tissue swelling of the right orbit, forehead, and ethmoid sinusitis, with rapid progression of swelling leading to increased intraorbital pressure, diplopia, and a dilated pupil unresponsive to light and diminished visual acuity. Surgical exploration revealed necrotic fascia and periosteum of the orbit. Cultures were positive for *A. haemolyticum* and orbital osteomyelitis was noted on pathology. He required three debridement surgeries, delayed wound closure, and prolonged intravenous antibiotics.

Ramey and Burket report a 20-year-old male who presented with pharyngitis, fatigue, malaise, and rash, was diagnosed with EBV infection, and received a course of oral steroids.⁶³ After 4 days of steroids, the patient had fevers, headache, right periorbital swelling, decreased extraocular motility, and blurry vision. He was diagnosed with orbital cellulitis and started on ceftriaxone. CT scans revealed deep subperiosteal fluid collection; MRI revealed extraconal, optic nerve sheath enhancement and hyperintensities, complete bilateral maxillary and ethmoid

opacification, and air fluid levels from both frontal sinuses. There was also pachymeningeal and leptomeningeal enhancement and subdural fluid collection. Despite sinus drainage and orbital exploration, he remained with orbital pain and proptosis with pupillary defect. Repeat imaging revealed reaccumulation of subperiosteal abscesses. This patient required multiple surgical procedures and drainage, in addition to prolonged antibiotics.

Burroughs and colleagues also present an 18-year-old man with pansinusitis, right orbital abscess, and rapid clinical deterioration, who had multiple abscess and sinus drainage procedures with sinus cultures positive for *A. haemolyticum* and orbital cultures positive for both *A. haemolyticum* and *Fusobacterium necrophorum*.⁸

The lessons from these cases alert clinicians that an early diagnosis requires high suspicion for this organism, and good communication with microbiology for appropriate measures to isolate this organism. Along with prolonged antimicrobial therapy, repeated debridement may be required for effective management.^{8,26,29,41,63–65,73}

Other Manifestations

Isolated instances of septicemia, brain abscess, meningitis, meningoencephalitis, orbital cellulitis, endocarditis, osteomyelitis, septic arthritis, deep soft tissue infections, pleural empyema, cavitory pneumonia, pyothorax, Lemierre disease, and sinusitis have been attributed to *A. haemolyticum* infection.* Most of these serious infections occurred in adults and frequently were associated with underlying conditions such as diabetes, a malignancy, or intravenous drug use. In a 1998 review of systemic and deep-seated infections caused by *A. haemolyticum*, Skov and associates⁷¹ identified two groups of patients. The first group was composed of middle-aged to elderly adults who were immunocompromised or had other known risk factors for development of serious infectious disease. The second group consisted of preteens to young adults with no known risk factors except for one individual receiving steroid treatment for Epstein-Barr virus infection. Theriault and colleagues⁷⁵ report a case of sepsis with *A. haemolyticum* bacteremia, cavitory pneumonia, and pyomyositis that resolved with combination therapy of penicillin and azithromycin in an 18-year-old man with only a past history of mild asthma. Cultures were positive for *A. haemolyticum* from blood, bronchoalveolar fluid, and surface and surgical cultures from a lower extremity abscess.

A pyothorax with multiloculated hydropneumothorax has been reported in a 19-year-old man in India with no history of pharyngitis.⁶⁰ Pure growth of *A. haemolyticum* was obtained from the thoracocentesis. Treatment consisted of a therapeutic thoracocentesis and continued chest tube drainage for 1 month. Ceftriaxone and metronidazole were given for a month, and the patient had clinical and radiologic resolution.

A brain abscess was documented in an 18-year-old man in Venezuela with history of multiple periodontal problems, with periodontitis, dental caries, and multiple tooth extractions.⁷⁶ The patient had headache, vomiting, and neurologic deficits in the left extremities. Computed tomography (CT) of the brain revealed a left-sided hypodense frontoparietal lesion with cystic, contrast ring enhancement, edema, and midline mass effect. With worsening neurologic status, a craniotomy was performed and aspiration of purulent material from the encapsulated mass revealed positive cultures with pure *A. haemolyticum* growth. Therapy consisted of ceftriaxone and metronidazole for 1 week and was switched after susceptibility testing to penicillin for 3 weeks.

Infective endocarditis caused by *A. haemolyticum* was reported in a 21-year-old woman with a history of congenital heart disease repaired as a child; she was on lifelong warfarin anticoagulation therapy.⁸³ This patient had fever, lethargy, and a swollen, painful left calf. A transthoracic echocardiogram raised concerns of vegetations on the mitral valve and ventricular septal defect patch. As a result of the occurrence of a grand mal seizure, a large right frontal parenchymal hematoma with smaller frontal abscesses was found on CT of the head. She required a frontal craniotomy for evacuation of the hematoma. Blood culture revealed *A. haemolyticum* in one of 12 sets, which was confirmed by 16S rRNA

*References 7, 23, 24, 37, 52, 54, 78, 82.

*References 2, 5, 8, 22, 26, 29–31, 33, 34, 40, 41, 44, 60, 63–65, 71, 73–75, 77–80, 83–85.

gene sequencing. Antimicrobial therapy consisted of ceftriaxone with addition of gentamicin, for 6 weeks total therapy. The initial therapy of vancomycin and metronidazole was given for only 2 weeks after identification of *A. haemolyticum*.

Fernandez-Suárez and colleagues²⁵ report that *A. haemolyticum* was associated with Lemierre's disease and septicemia in a 23-year-old man who presented with acute pharyngotonsillitis. The patient underwent cervical contrast-enhanced CT, which revealed complete thrombosis of the left internal jugular vein. Enoxaparin was initiated, with a transition to another anticoagulant (acenocoumarol) for 3 months as an outpatient. Antimicrobial therapy consisted initially of high-dose amoxicillin-clavulanate and metronidazole, but was changed to imipenem-cilastatin and metronidazole when right basal pneumonia was diagnosed, along with bilateral pleural effusions. The patient completed 7 days of intravenous antibiotics and was transitioned to clindamycin as an outpatient for 10 days. All three blood cultures were positive for *A. haemolyticum*.

Lemierre disease with coinfection of *A. haemolyticum* and *Fusobacterium necrophorum* bacteremia was reported by Younus and colleagues.⁸⁵ A 21-year-old man presented with fever, sore throat, tenderness along the border of his left sternocleidomastoid muscle, crackles, a blanching maculopapular rash, sepsis, and worsening pulmonary symptoms. The initial blood culture had *F. necrophorum*, and repeat blood cultures from day of admission had *A. haemolyticum* before antimicrobial therapy. CT of the chest revealed multiple nodular densities in the lungs, with evidence of central necrosis in one area. Therapy consisted of anticoagulation with heparin, initial antimicrobial therapy of gatifloxacin and metronidazole, which was switched to vancomycin and piperacillin-tazobactam for 2 weeks, followed by an oral course of amoxicillin-clavulanate for 3 months, but no surgical intervention was needed.

Sayyahfar et al. report a 2-year-old girl with a thyroid abscess who presented with fever without a source for 10 days but was eventually noted with a painful neck mass.⁶⁹ She had a CT scan that revealed a cystic lesion in the left thyroid lobe causing tracheal shift, compatible with abscess. This patient had surgical exploration and aspiration of the abscess after 2 days of antibiotics; cultures revealed *A. haemolyticum*. She was treated with clindamycin and ceftriaxone before surgery and transitioned to clindamycin to complete oral therapy.

DIFFERENTIAL DIAGNOSIS

Pharyngitis caused by *A. haemolyticum* must be differentiated from all other causes of pharyngitis (see Chapter 9). Of particular importance is distinguishing *A. haemolyticum* pharyngitis from *S. pyogenes* pharyngitis. Such differentiation can be achieved with certainty only by specific culture. In *A. haemolyticum* infection, the rapid group A streptococcal antigen tests will be negative, as will the usual group A streptococcal culture. These negative tests in specimens from adolescents should suggest strongly the possibility of *A. haemolyticum* pharyngitis.

When exanthem occurs, the confusion with illness caused by *S. pyogenes* is more pronounced. In many cases, the rash in patients infected with *A. haemolyticum* is scarlatiniform. However, the lack of typical circumoral pallor and a tendency for more discrete lesions in *A. haemolyticum* infection occasionally may help in making the clinical diagnosis.

Other common causes of pharyngitis and exanthem in adolescents and young adults are *Mycoplasma pneumoniae* and Epstein-Barr virus infections. As noted by Mackenzie and colleagues,⁴⁵ *A. haemolyticum* and Epstein-Barr virus coinfections are not uncommon occurrences. Concurrent *M. pneumoniae* pneumonia and *A. haemolyticum* empyema and bacteremia have been reported in a previously healthy 20-year-old man.⁷²

Cutaneous infections, including subacute ulcerations, wound infections, cellulitis, and paronychia caused by *A. haemolyticum*, must be differentiated from those caused by other organisms, such as staphylococci and streptococci.

SPECIFIC DIAGNOSIS

A specific diagnosis is made by culturing *A. haemolyticum* from the pharynx, a skin lesion, or a sterile body site in invasive infections. Culturing is done best with rabbit or human blood agar and the addition of 5% carbon dioxide.^{19,21,78,81} An important note is that horse or sheep blood agar, which generally is used for culture of *S. pyogenes*, is not satisfactory for the growth and identification of *A. haemolyticum*. Using biochemical identification systems, such as the API (RAPID) Coryne strip or the Biolog system, can help differentiate *A. haemolyticum* from other coryneform bacteria. The Biolog system can make the identification in 4 hours.²⁷

TREATMENT

A. haemolyticum is highly susceptible to numerous antibiotics.^{10,13,46,57,78} Although no specific treatment studies have been performed, the experience in several large studies suggests that both penicillin and erythromycin are effective.^{10,36,46,51} Clinical failure with penicillin has been noted.^{3,55,78} Therefore, erythromycin has been suggested for first-line therapy for certain indications, such as *A. haemolyticum* tonsillitis.¹² Carlson and coworkers¹² suggest using either a broad-spectrum β -lactam antibiotic, clindamycin, or macrolides for serious systemic *A. haemolyticum* infections, although these authors do acknowledge that macrolides do not provide anaerobic coverage. An alternative approach would be to use high-dose penicillin plus an aminoglycoside.^{71,78}

PROGNOSIS

The prognosis in cases of *A. haemolyticum* pharyngitis is good, even in untreated patients. However, invasive disease can be fatal, and peritonsillar abscess or sinusitis with orbital cellulitis requires prompt surgical intervention and appropriate antimicrobial therapy.

Erysipelothrix rhusiopathiae (*insidiosa*) was identified definitively first by Rosenbach⁴⁰ in 1884 as a cause of the cutaneous disease erysiploid. Although most commonly associated with localized skin infection in humans, this organism has been associated with sepsis,^{17,38,50} chronic skin eruption,^{12,24} and endocarditis.^{4,17,30,31,39,50}

BACTERIOLOGY

E. rhusiopathiae is a slender, pleomorphic, gram-positive, unencapsulated rod that produces 0.1-mm bluish colonies on blood agar. On Gram staining, the rods may appear singly, in short chains, or, rarely, in long branching filaments. Although they are gram positive, they decolorize readily, sometimes producing a spotted appearance. Some strains produce α -hemolysis in 48 to 72 hours. Gelatin inoculated by stab inconsistently forms a “test-tube brush” or “pipe cleaner” appearance diagnostic for this organism.¹⁷ *Erysipelothrix* is differentiated from morphologically similar *Listeria monocytogenes* and diphtheroids by the absence of motility and catalase production and by the presence of hydrogen sulfide production in triple-sugar iron medium.^{17,50}

EPIDEMIOLOGY

First isolated from mice in 1880 by Koch, *Erysipelothrix* is a common commensal of wild and domestic mammals, birds, and fish.^{17,50} The organism also may lead a saprophytic existence in soil. First identified by Loeffler in 1882 as the causative agent of swine erysipelas, it remains an important epidemic cause of disease in these animals.¹⁷ Sheep, rabbits, cattle, turkeys, and rats are subject to infection. *Erysipelothrix* has been recovered from wild moose and domestic emus.^{7,18,28} *E. rhusiopathiae* survives salting and smoking procedures. Pieces of meat may contain the organism for 170 days after pickling, but exposure to moist heat for 15 minutes at 55°C kills most strains.^{17,48} Fish handlers, meat processors, poultry workers, veterinarians, abattoir workers, and food handlers are at risk for exposure to *Erysipelothrix*.^{33,35} Almost 90% of cases are linked to high-risk occupational exposures.²² Isolates of the same serotype may show genetic diversity, thus serotyping may not be completely reliable as an epidemiologic tool for tracking outbreaks.⁸

PATHOPHYSIOLOGY

Human infection is largely accidental and results from contamination of skin abrasions during handling of infected material. Males are infected more commonly than females, perhaps because of an increased risk for exposure. The presence of an antiphagocytic capsule may be a virulence factor for *E. rhusiopathiae*.⁴³ In vitro study shows that encapsulated strains are poorly phagocytized by macrophages, unless immune serum is provided; ingested bacteria are able to replicate within the macrophage. Knock-out isolates that lack surface protective antigen A (SpaA) are 76-fold less virulent and are sensitive to the bactericidal activity of swine serum.⁵ The ability to survive and replicate within macrophages probably is due to failure of the encapsulated strains to induce the oxidative burst;⁴² full genomic sequencing shows that *E. rhusiopathiae* encodes for nine antioxidant factors and nine phospholipases that facilitate intracellular survival.³⁶ The disease usually is self-limited, most often involving the hands. Biopsy of skin lesions shows a marked inflammatory response. Difficulty establishing bacteriologic confirmation has been attributed to the organism's location in the deep part of the pars reticularis of the corium.¹⁰

CLINICAL MANIFESTATIONS

Human disease typically manifests as a mild, localized cutaneous eruption; a more severe, generalized cutaneous form; or a septicemia often associated with endocarditis. Localized cutaneous infection, the erysiploid of Rosenbach,⁴⁰ is the most common manifestation of *Erysipelothrix* disease.³⁵ After a 1- to 4-day incubation period, an acute localized lesion appears at the site of an abrasion contaminated with *E. rhusiopathiae*-colonized material. Slowly progressive, purplish red, painful induration is typical. Absence of suppuration and involution without desquamation help to distinguish this lesion from streptococcal or staphylococcal infections. Occasionally, the skin may show sharply circumscribed bluish red lesions, which are similar to the cutaneous manifestations in swine.^{17,50} Fever and other constitutional symptoms are uncommon manifestations, occurring in less than 10 % of cases, unless bacteremia supervenes.^{12,35} Untreated infection usually is self-limited, with an average duration of 3 weeks.

Lymphangitis and adenitis occur in 10% of cases; in 20% of cases, progression of disease extends from lesions on the hand to the wrist and forearm.²⁵ In one case, a patient with type 2 diabetes was discovered at the time of surgery to have necrotizing fasciitis; *E. rhusiopathiae* was the predominant but not only organism isolated from surgical specimens.⁴⁴ A 7-week-old infant with localized *E. rhusiopathiae* infection of the knee without a known source of exposure has been reported,²⁷ and a 6-year-old girl with *Erysipelothrix* pyopneumothorax has been described.³⁷ Septic arthritis has been described in a healthy 18-year-old man in whom disease developed after he underwent arthroscopic knee surgery,² in association with infective endocarditis,⁴¹ and in a patient with systemic lupus erythematosus and chronic monoarthritis without associated systemic symptoms.⁴⁹ One case of septic arthritis of the hip in a 5-year-old boy without risk factors or obvious immune deficiency has been reported.³²

Cutaneous eruptions may occur rarely in areas distant from the site of inoculation,²⁶ appearing as violaceous lesions with advancing pink borders. Bullous vesiculation has been described.¹² In 1921, Prausnitz³⁸ reported the first case of apparent septicemia in childhood, isolating the organism from the blood of a 10-year-old boy.

E. rhusiopathiae rarely is associated with the bite of a domestic dog or cat.¹ In one prospective study of infected domesticated animal bite wounds, two patients who had been bitten by a cat infected with *E. rhusiopathiae* were identified.⁴⁵ Cultures were carefully processed and were performed in reference laboratories. Cats are not natural hosts of the organism.

An uncommon but important complication of *Erysipelothrix* infection is endocarditis. Presumed or proven endocarditis accounts for 90% of serious *E. rhusiopathiae* infections.¹⁶ Patients with congenital heart disease or heart valve damage secondary to acute rheumatic fever are at the greatest risk for development of endocarditis. However, previously normal heart valves can be infected.^{17,30} Valvular and myocardial abscesses have been described.³⁴ In contrast to diphtheroid endocarditis, *E. rhusiopathiae* endocarditis usually does not involve prosthetic valves; and in contrast to *Bacillus* spp. endocarditis, it is not associated with intravenous drug abuse.¹⁶ In a review of 1989 cases of endocarditis from 13 series,⁴ *Erysipelothrix* was documented in two patients. *Erysipelothrix* endocarditis commonly involves the aortic or mitral valves or both. Overall mortality in reported cases is 38%, despite appropriate surgery and antibiotic therapy, which is considerably higher than that associated with other pathogens of endocarditis.¹⁵ Many patients with endocarditis are treated empirically with vancomycin, a drug to which all *Erysipelothrix* isolates are constitutively resistant.²⁰ No history nor

vancomycin resistance

physical evidence of cutaneous lesions is found in 50% of cases of endocarditis, and history of exposure to contaminated material often is lacking. Although immunocompromised individuals³¹ may be at increased risk, serious infection also occurs in otherwise normal hosts,^{6,17,30} particularly in association with occupational exposure. Many case reports involve patients with diabetes mellitus and/or alcoholic hepatitis.

Multiple case reports of septic arthritis, usually involving prosthetic joints, have been published.^{19,46,47} In rare cases, *E. rhusiopathiae* can cause pneumonia,²⁹ osteomyelitis,⁹ spinal abscess,³ or meningitis.²¹ Meningitis may be acute²¹ or chronic.²³

DIAGNOSIS

For localized disease, diagnosis depends largely on clinical appearance of the lesion in association with an appropriate history of exposure. Attempts to culture the organism from material collected by swab or aspirate of a local lesion almost always are unsuccessful.^{10,50} Biopsy specimens of affected skin cultured in broth generally yield the offending bacteria. Amplification and detection of *Erysipelothrix* DNA by polymerase chain reaction show promise in animal models of infection.²⁸ Other newer mechanisms for identification include matrix-assisted laser desorption ionization-time of flight (MALDI-TOF)¹³ and loop-mediated isothermal amplification (LAMP) assays.⁵¹ *Erysipelothrix* is isolated commonly from the blood of patients with septicemia or endocarditis and can be found in affected heart valves at autopsy or at the time of valve replacement.¹² Growth of the organism may be slow; cultures should be monitored for at least a week. A high index of suspicion is important for establishing the diagnosis of endocarditis. The organism has been misidentified as a viridans group streptococcus because of its pleomorphic coccoid appearance, α -hemolysis, and catalase-negative character. Abbreviated identification schema that do not include testing for hydrogen sulfide production sometimes lead to misidentification as *Lactobacillus* spp. or enterococci.¹¹

TREATMENT

E. rhusiopathiae is exquisitely sensitive to penicillin. Most isolates also are sensitive to ceftriaxone.¹⁴ Clindamycin or ciprofloxacin may be used for patients who are allergic to penicillin.¹⁴ Localized disease usually can be treated with oral medication, but high parenteral doses occasionally are necessary, particularly for disseminated disease.¹⁷ Treatment of

endocarditis is similar to treatment of endocarditis caused by viridans streptococci. At least 12 million units of penicillin administered for 4 weeks has been curative in adult patients, but many cases have been treated for 6 weeks or longer. Concomitant administration of an aminoglycoside has been used in some cases. *Erysipelothrix* is resistant to vancomycin.²⁰ Prompt microbiologic differentiation of *E. rhusiopathiae* from other gram-positive organisms is important in guiding antimicrobial choice because vancomycin often is employed in empiric therapy of endocarditis. Risk of disease is minimized by protecting individuals exposed to potentially contaminated materials.

Listeriosis

Sing Sing Way • Ghada N. Al-Rawahi • Tobias R. Kollmann

Listeria species are found widely in the environment in soil, water, and decaying vegetation.^{4,46,124} Pathogenic *L. monocytogenes* was described first by Murray and associates in 1926 while investigating an epidemic of fatal infections in laboratory rabbits during pregnancy.¹⁰⁰ The first case of human *L. monocytogenes* infection was identified 3 years later,¹⁰² with neonatal infection first recognized in 1936.¹⁷ The first outbreak confirming transmission from animals to humans was reported in 1983.¹²⁵ *L. monocytogenes* is now recognized as a ubiquitous bacterium that colonizes the intestinal tract of virtually all mammalian species. It has specialized virulence features that make it an often lethal pathogen in a wide variety of susceptible hosts, including newborn infants, pregnant women, older adults, and other individuals with immunocompromising conditions.^{14,27,80} The frequent occurrence of outbreaks underscores the necessity for the continued high level of attention afforded to this organism.¹⁸

ORGANISM

The genus is named after Sir Joseph Lister, the pioneer of antiseptic surgical techniques.¹³² *Listeria* are facultative anaerobic, non-spore-forming, motile, small gram-positive bacilli that form whitish-gray colonies with narrow zones of β -hemolysis on nutrient agar. They are catalase positive, non-acid-fast and non-capsule-forming bacteria. Of the nineteen defined species within the *Listeria* genus,³⁷ the majority of clinical infections are caused by *L. monocytogenes*.^{58,87} The few case reports on human infection caused by other species usually involve immunocompromised hosts.¹²¹ In direct smears, *Listeria* may have a coccoid morphology and be confused with Gram positive cocci. However, the following features of *L. monocytogenes* may be used to distinguish it from other Gram-positive bacteria¹³¹:

1. All *Listeria* species exhibit tumbling motility at 25°C to 30°C, owing to the uniform distribution of flagella across the bacterial surface (peritrichous) flagella, with reduced motility at 37°C (98.6°F).¹⁵⁵

2. *L. monocytogenes* grows with a narrow zone of β -hemolysis (non-hemolytic, non-invasive mutant strains exist but are rare⁶⁷) and exhibits a rectangular area of increased hemolysis when streaked on blood agar in proximity to *Staphylococcus aureus* (Christie, Atkins, Munch-Peterson [CAMP] test).
3. *L. monocytogenes* ferments methyl-D-mannoside and L-rhamnose but not D-xylose.

Listeria tolerate low temperatures, high salt concentrations, and high pH, which allows survival and replication in soil, water, sewage, manure, animal feed, and refrigerated foods. Cold enrichment has been used to improve isolation from clinical samples.^{11,45,58,130} In this regard, the ability of *Listeria* to survive and replicate even at refrigeration temperatures distinguishes it from most other food-borne bacterial pathogens. Paterson,¹⁰⁷ and Seeliger and Finger¹³³ performed extensive serologic characterization of *L. monocytogenes*. At least 17 serotypes have been identified on the basis of somatic and flagellar antigens, with 3 (1/2a, 1/2b, 4b) accounting for most clinical and food isolates.^{92,109}

TRANSMISSION

The ability of *L. monocytogenes* to tolerate high salt concentrations and an alkaline environment allows it to survive for months in soil, water, animal feed, and refrigerated foods.²⁵ Contaminated food is the most common source of human *Listeria* infection.^{20,54,78} Despite implementation of a “zero tolerance” policy for *L. monocytogenes* by the US Department of Agriculture in 1987, outbreaks involving various meat and dairy products, along with contaminated fruits and vegetables, remain common.¹⁸ *L. monocytogenes* still is the most common cause of foodborne illness–related hospitalization and death in the United States.²⁰ Nonetheless, despite frequent foodborne outbreaks, most infections are sporadic and have no epidemiologic explanation.¹⁴⁹ These sporadic clinical cases could reflect invasive infection from intestinal colonization. Indeed, the rate of asymptomatic fecal carriage in healthy individuals is common, ranging from 2% to 10%¹²⁴ or higher.^{66,80} However, fecal shedding of *L. monocytogenes* appears to be of short duration.⁵⁴ Although maternal colonization does not invariably lead to invasive illness, pregnancy-associated infection represents approximately 17% of all invasive cases.⁶¹ About 20% of pregnancy-associated infection results in stillbirth or neonatal death.⁶¹ Transmission of *L. monocytogenes* from mother to fetus can occur in utero by ingestion of infected amniotic fluid or transplacentally from the maternal circulation.⁸⁰ The factors contributing to cases of late-onset infection of the newborn (up to 2 months of age) are unknown.^{12,69,111}

EPIDEMIOLOGY

Despite its ubiquitous presence and frequent sporadic outbreaks, *L. monocytogenes* is a relatively uncommon cause of infection in the general population (ranging from 0.1 to 10 per 1 million individuals).^{14,27,44,120,140} Listeriosis has a nonuniform age distribution, with most cases occurring among newborn infants or older adults (Fig. 95.1). In these susceptible subpopulations, infection confers a disproportionately high mortality rate ranging from 20% to over 60%.¹²⁰ Invasive *L. monocytogenes* infection is also 20- to 100-fold more common among women during pregnancy compared with the general population.^{51,61,80} As a result, perinatal attack rates during outbreaks are extremely high and can reach 1% to 2% of all deliveries.^{12,111} Although preventative measures, monitoring, and voluntary recall of contaminated food products have reduced the incidence of perinatal listeriosis in recent decades,⁸⁰ risk for foodborne infection remains high, with increasing incidence in older adults.^{12,94,120}

PATHOGENESIS AND PATHOLOGY

Listeria is a facultative intracellular organism. Infection with *L. monocytogenes* begins after oral ingestion of the bacteria. In adults, the infectious dose is estimated to be 10^4 to 10^6 organisms per gram of ingested food but may be as low as 10 organisms in immunocompromised hosts and patients who have diminished gastric acidity or injured intestinal barrier function.^{124,126,12,123} *L. monocytogenes* infects intestinal M cells through phagocytosis and intestinal epithelial cells through actions of listerial surface proteins called internalin A (InlA).^{43,84} InlA binds to host E-cadherin that is transiently exposed to the luminal surface of the intestinal villi during remodeling of epithelial junctions.¹⁰⁸ InlA also facilitates placental invasion since E-cadherin is expressed on syncytiotrophoblasts.^{10,85} After intestinal epithelial cell invasion, *L. monocytogenes* translocates systemically to infect target tissues that include the liver, spleen, mesenteric lymph nodes, and other organs via the blood and lymph.¹⁵⁰ Binding of listerial internalin B (InlB) to the host hepatocyte growth factor receptor (also known as the tyrosine kinase receptor Met) and complement component C1q⁸ permits efficient hepatocyte entry via endocytosis.^{15,16,31,53,105} InlB may also have a role facilitating the transfer of *L. monocytogenes* across the blood-brain barrier.⁵³

After cell entry, *L. monocytogenes* quickly escapes from endocytic vacuole and enters the cytosol of host cells. In the cytosolic compartment, the bacterium replicates and spreads to adjacent neighboring cells through intercellular protrusions, avoiding recognition and subsequent destruction

FIG. 95.1 Human listeriosis cases by age group for the United States, 1970–71 and 1980–81. (From Albritton WL, Cochi SL, Feeley JC. Overview of neonatal listeriosis. *Clin Invest Med*. 1984;7:311–314.)

* Age unknown for 63 cases

** Age unknown for 3 cases

by antibodies or neutrophils.⁷⁹ *L. monocytogenes* vacuolar escape is mediated by two virulence-associated bacterial proteins: listeriolysin O (LLO) and phospholipase C.²⁵ LLO is a pore-forming, cholesterol-dependent cytolysin.^{7,70,127,151} Although LLO is absolutely required for vacuolar escape in murine cells, it appears dispensable in human cells, where phospholipases play unique and functionally redundant roles.¹¹⁰ Once in the host cell cytoplasm, *L. monocytogenes* retains motility by active recruitment and polymerization of actin filaments into organized tails though the actin assembly-inducing protein ActA. Motile bacteria create membrane-bound protrusions into adjacent cells; within the newly infected cells, the membrane layers are then lysed by LLO and phospholipases, propagating the unique intracellular life cycle of this bacterium. Thus, key *L. monocytogenes* virulence determinants include efficient invasion and access to the cytoplasmic compartment of host cells, followed by rapid spread into adjacent cells, thereby avoiding intracellular degradation (autophagy) as well as extracellular host defense mechanisms (e.g., antibodies, complement, neutrophils).^{97,143–145} In animal infection models, *L. monocytogenes* mutants lacking the molecules required for cytoplasmic entry from the endocytic vacuole (e.g., LLO or phospholipase C) or actin recruitment within the host cell cytoplasm (ActA) are highly attenuated.¹⁵¹ Although ActA is one of the major virulence determinants of *L. monocytogenes*,²⁹ strains lacking ActA retain the ability to infect the placenta, although at a lower rate than wild-type strains.⁸³

To counteract infection, a protective host response that aims to restrict bacterial invasion and survival is set into motion shortly after *L. monocytogenes* host cell adherence.^{25,148} This has been best characterized after infection of mouse macrophage cells, where *L. monocytogenes* activates at least three unique host defense pathways¹⁵⁷: (1) a MyD88-dependent pathway emanating from the cell surface and phagosome, leading to expression of cytokines and reactive oxygen species; (2) a STING/IRF3-dependent pathway emanating from the cytosol, leading to the expression of interferons and coregulated genes; and (3) an AIM2/caspase-1-dependent inflammasome pathway, resulting in proteolytic activation and secretion of interleukin (IL)-1 and IL-18 and pyroptotic cell death. *L. monocytogenes*, on the other hand, has developed elaborate mechanisms to counterbalance these host defense strategies.²⁸ The outcome of this molecular “tug of war” is likely dictated by the bacterial inoculum and activation properties of individual host cells.

Cytokines and chemoattractant chemokine proteins released by *L. monocytogenes* infected cells recruit neutrophils, which efficiently eliminate extracellular bacteria and dying infected cells.⁷⁵ Infected macrophage cells also produce the proinflammatory cytokine IL-12, which induces the synthesis of interferon- γ (IFN- γ) by natural killer cells and CD4 T helper-1 cells. IFN- γ in turn activates infected macrophages to become listericidal through the production of free oxygen and nitrogen radicals.^{104,150} The recruitment of acute inflammatory cells to local sites of infection with *L. monocytogenes* in some cases results in granulomas, thereby containing and limiting further spread of the infection.¹³⁴ Although multiple granulomas are characteristic of disseminated disease, suppurative inflammation is more common.⁷⁴ These innate immune effector cascades limit the spread of *L. monocytogenes* during the early phase of infection. In the immune-competent host, adaptive T-cell immune responses peak about 1 week after primary infection, leading to complete clearance of infected cells; this process also leads to acquired resistance to subsequent infection (immune memory).¹⁰⁴ Acquired immunity is not dependent on clinical symptomatic infection, because T cells specific for *L. monocytogenes* are frequently present in healthy individuals without a history of listeriosis.^{26,47,77,98,111,112}

There are many poorly defined shifts in immune responsiveness that occur during pregnancy, the neonatal period, and in elderly individuals that contribute to infectious susceptibility.^{76,86,101} Importantly, the host response in humans to *Listeria* infection has not been studied in sufficient detail to determine what specific aspect of immune-mediated protection fails to protect those most susceptible from severe listeriosis. Nonetheless, investigation using preclinical infection models suggests that susceptibility to invasive *L. monocytogenes* infection during pregnancy is primarily conveyed by the selective expansion of immune suppressive regulatory CD4 T cells that are essential for maintaining maternal tolerance to genetically foreign paternal antigens expressed by the developing

fetus.^{35,64} Fetal wastage readily occurs with systemic maternal *L. monocytogenes* infection in animals. However, fetal wastage does not require *L. monocytogenes* invasion of the placental unit, but instead is driven by fractured maternal tolerance to immunologically foreign fetal antigens.^{117,119} Disrupted fetal tolerance with ensuing inflammation at the maternal-fetal interface draws circulating pathogen into the placenta, bypassing innate host resistance properties of trophoblast cells and other cell types unique to this tissue.^{115,158,159} These recent findings demonstrating a causative role for “unintentional” attack by maternal immune components in driving fetal wastage that occurs with prenatal infection also highlights the exciting possibility of protecting the developing fetus from injury using immune modulatory therapies.^{21,118} In turn, naturally occurring strategies for reinforcing fetal tolerance, including immunological tolerance to noninherited maternal antigens, have recently been shown to protect against fetal injury and congenital transmission after *L. monocytogenes* prenatal infection.^{72,73}

In animal models of neonatal infection, *L. monocytogenes* susceptibility is associated with blunted production of innate proinflammatory cytokines, and delayed activation of protective T cells.¹² Recently, active immunological suppression by erythroid precursor cells that express the transferrin receptor, CD71, has been shown to play a dominant role skewing neonatal T cell differentiation towards susceptibility of newborns to invasive infection by *L. monocytogenes* and other neonatal pathogens.^{34,114} However, the physiological enrichment of erythroid precursor cells in early postnatal development that increase susceptibility to *L. monocytogenes* and other neonatal pathogens may play more essential roles in averting pathological inflammation during primary colonization with commensal microbes during the abrupt transition from the sterile in utero compartment that occurs with parturition.³⁴ Therefore, the susceptibility of neonates to invasive infection by *L. monocytogenes* and other neonatal pathogens likely reflects the need for active immunological suppression during this unique developmental window.

In older children and young adults, *L. monocytogenes* infection is rare; however, underlying diseases or medications that interfere with cell-mediated immunity are known to increase susceptibility.^{12,24,30,60,111,135,148,157} On the other hand, neutropenia and disorders of the humoral immune system (complement or immunoglobulin) are not associated with excessive prevalence of listeriosis.⁸⁰ This suggests a central role of at least the innate and adaptive cell-mediated immune system in optimal defense against *L. monocytogenes* in the human host.

CLINICAL MANIFESTATIONS

The incubation period for listeriosis is variable, ranging from 6 hours to 10 days for gastroenteritis to 1 to 70 days for invasive disease.^{89,103} Most infections with *L. monocytogenes* in the healthy host remain entirely asymptomatic.¹² Clinical infection with *L. monocytogenes* is called listeriosis¹²³ and exists in two forms depending on the immunologic status of the host: noninvasive gastrointestinal listeriosis and invasive listeriosis.^{12,120,151} In immunocompetent children and adults, noninvasive listeriosis develops as a febrile gastroenteritis.^{123,126} However, in vulnerable groups, including women during pregnancy, the developing fetus, neonates, and infants up to approximately 2 months of age,⁸⁸ older adults (>60 years of age), and immune-compromised children and adults with impaired cell-mediated immunity,^{12,120} *L. monocytogenes* more readily disseminates from the gastrointestinal tract into the systemic circulation and from there to other tissues.¹² The main target tissues include the placenta, the central nervous system, liver, and spleen.^{12,32,111,123} This clinical pattern of invasive listeriosis derives from the unique capacity of *L. monocytogenes* to cross the placental, intestinal, and blood-brain barriers.⁸⁴

In pediatric listeriosis, most severe infections occur in the first 2 months of life. Similar to those of group B streptococcal infection, the initial clinical features of neonatal listeriosis can be divided into early and late-onset disease (Table 95.1). In 50% to 74% of early-onset cases, the mother reports a history of an “influenza-like illness,” with 65% reporting fever, 21% backache (which may be mistaken for a urinary tract infection), 10% headache, 7% vomiting and diarrhea, and 4% muscle pains or sore throat. Importantly, despite this range of clinical symptoms, approximately one-third of infected pregnant women remain

TABLE 95.1 Clinical and Laboratory Findings of Early-Onset and Late-Onset Neonatal Listeriosis

Feature	Early Onset ^{80,65,1,3,39}	Late Onset ^{2,40,71,80,128}
Median (range) age (days)	1 (birth to 6)	14 (7–35)
Male (%)	60	67
Preterm (%)	65	20
Mortality rate (% range)	38 (22–63)	3 (0–10)
Respiratory involvement (%)	38–50	10
Meningitis (%)	24	67–93
Blood isolate (%)	81–88	17–95
Maternal perinatal illness (%)	50–74	0

**FIG. 95.2** Typical pustular rash on the abdomen of a stillborn infant with listeriosis. Note the small pale granuloma measuring 1 to 3 mm and the dark erythema surrounding these lesions.

entirely asymptomatic.⁸⁰ Spontaneous abortion occurs in 10% to 20% of clinically symptomatic listeriosis cases during pregnancy, with another approximately 50% delivering preterm, and 11% ending in intrauterine fetal demise.⁸⁰ Thirty-four percent of infected pregnancies demonstrate fetal distress, and 75% display meconium-stained amniotic fluid; microabscesses are frequently histologically evident in infected placentas.⁸⁰

Early-onset neonatal listeriosis has a high mortality rate (20–60%); even in those who survive, a significant number (12.7%) develop long-term neurologic sequelae.^{12,80} At birth, respiratory distress, apnea, lethargy, and fever are common manifestations; diarrhea, conjunctivitis, and myocarditis also have been described.¹² The respiratory symptoms may mimic symptoms of respiratory distress syndrome. Patchy bronchopneumonic infiltrates, probably caused by aspiration of infected amniotic fluid, may be seen on chest radiographs.¹² Occasionally, discrete roseolar or pustular lesions on the skin and pharynx occur that on histology appear as microabscesses and macroabscesses and contain culturable *L. monocytogenes*; this rash has been termed *granulomatosis infantisepsiticum* (Fig. 95.2).

The late-onset form of neonatal listeriosis is less common than the early-onset form and usually affects term infants, who appear healthy

until the onset of meningitis or, less commonly, septicemia and colitis 1 to 8 weeks after birth.^{40,59,71,81} Clinical manifestations of late-onset meningitis are often subtle and include fever, irritability, lethargy, and poor feeding.^{71,129} Cerebrospinal fluid findings vary; although pleocytosis usually is significant, not all infections have a polymorphonuclear cell predominance. The maternal history in these cases usually is negative, suggesting postnatal, possibly even nosocomial, exposure in affected infants.¹³⁰

Although the incidence of listeriosis in immunocompromised children is higher, the clinical features are similar to those of non-immunosuppressed patients and include most commonly meningitis or septicemia. Rare clinical manifestations of *L. monocytogenes* infection include rhombencephalitis, brain abscess, arthritis, osteomyelitis, endocarditis, endophthalmitis, liver abscess, and peritonitis.^{90,129,130,135}

DIAGNOSIS

Appropriate specimens for staining and culture vary with the clinical syndrome, but the organism can be readily cultured from blood, cerebrospinal fluid, amniotic fluid, and genital secretions. Examination of gram-stained material (ear, meconium, and placenta) from neonates is recommended in suspected, early-onset sepsis.⁸³ Pathologic specimens (e.g., biopsy material, placental or fetal tissue) may reveal the characteristic Gram-stain morphology and pathologic features, such as microabscesses and granulomas. Selective and differential culture media, such as lecithin and levofloxacin (LL) medium, CHROMagar *Listeria*, PALCAM (polymyxin B–acriflavine–lithium chloride–ceftazidime–esculin–mannitol agar) or modified Oxford agar, may be helpful for isolation of *Listeria* from nonsterile sites such as stool or vaginal secretions.^{91,106,109} Laboratories undertaking primary isolation must be aware of the similarities between *L. monocytogenes* and frequently disregarded “commensals.”⁹²

After 48 hours of incubation at 37°C on 5% sheep blood agar, typical colonies are whitish/gray with a narrow zone of β -hemolysis. Traditionally, identification is based on morphology; tumbling motility; β -hemolysis; positive catalase, esculin, and CAMP tests; and carbohydrate-use pattern. Commercial kits are available for the rapid identification of *Listeria* from culture. These kits include DNA probes, latex agglutination, and enzyme immunoassay methods. Despite extensive attempts to develop serologic techniques for the diagnosis of listeriosis, none has proved satisfactory and few centers attempt serodiagnosis. More recently, matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) has become a valuable tool for the rapid identification, and possibly typing, of *Listeria* species.^{6,62}

Histologic diagnosis from pathologic material should be attempted if the organism is not cultured. Specific fluorescent antibody staining,²² nucleic acid hybridization,¹³⁹ and polymerase chain reaction^{5,63} have all been used for detection of *Listeria*. The application of molecular detection to food safety programs has been growing rapidly, with clinical applications of molecular *Listeria* detection lagging somewhat behind with regard to the limited commercial options available. However, several centers have reported the development of sensitive and specific molecular assays for detection of *L. monocytogenes* in cerebrospinal fluid. For cases of suspected meningitis with prior antibiotic treatment, broad-range 16S rDNA polymerase chain reaction is becoming widely used in North America and can be key in establishing the diagnosis.^{13,82}

TREATMENT

Intravenous ampicillin and an aminoglycoside, typically gentamicin, remain the treatment of choice for invasive *L. monocytogenes* infections. Ampicillin may be used alone in immunocompetent patients with less severe infections or once clinical response has occurred. *L. monocytogenes* shows tolerance to some antibiotics in vitro,^{36,93} but antibiotic resistance in clinical *Listeria* isolates remains low (although surveillance of food and dairy products has shown an increase in resistance to multiple antibiotics including ampicillin).^{55,137,154} Ampicillin plus gentamicin has demonstrable synergy on most *Listeria* strains both in vitro and in animal models^{33,96,146}; however, human clinical trial data for dual treatment are lacking. Antibiotics commonly recommended

for treatment—including ampicillin—are bacteriostatic at concentrations usually achieved in blood.^{36,48,49,147,152}

For penicillin-allergic patients, trimethoprim-sulfamethoxazole has been used successfully.^{54,138} This is supported by in vivo data with and without the addition of rifampin.^{41,56,57,96,122} In an in vivo model of *L. monocytogenes* encephalitis, the combinations ampicillin/gentamicin and trimethoprim-sulfamethoxazole/rifampin were highly active against intracerebral bacteria.⁹ Trimethoprim-sulfamethoxazole cannot be recommended for use in perinatal infections because of the concern of bilirubin toxicity developing with sulfonamides.⁴¹

For patients with both penicillin and sulfa allergies, vancomycin has been used successfully, albeit with much less accumulated clinical experience than ampicillin-based regimens.¹¹³ One group has reported a case of bacteremia with vancomycin-resistant *L. grayi*, the first such documented invasive infection with this species.¹²¹ More recently, cases of invasive *Listeria* infections treated successfully with linezolid have been published; this oxazolidinone antimicrobial exhibits bactericidal activity against *Listeria*.^{96,99}

L. monocytogenes is intrinsically resistant to cephalosporin antibiotics.³⁶ Acquired resistance to clindamycin, tetracyclines, quinolones, macrolides and daptomycin has been reported, although clinical experience with these agents is very limited.^{95,136,156} Antagonism also seems to occur between certain antibiotic combinations (erythromycin and penicillins, erythromycin and aminoglycosides, penicillin and chloramphenicol, and penicillin and tetracycline).^{36,48}

Duration of therapy depends on the clinical syndrome, the presence of underlying disease, and the response to treatment. For most invasive infections without meningitis, 10 to 14 days of therapy is usually sufficient. When meningitis is present, many experts recommend 2 to 3 weeks of therapy. Longer courses may be necessary for patients with endocarditis, rhombencephalitis, and severe complicated infections. When treating central nervous system infections, diagnostic imaging of the brain near the end of anticipated therapy may be used to evaluate the possibility of parenchymal involvement and determine the need for an extended duration of therapy.

Listeria gastroenteritis in otherwise healthy individuals is generally a self-limited illness, and no data exist with regard to the efficacy of antimicrobial therapy. In high-risk individuals such as pregnant women and immunocompromised patients, who have either symptomatic illness or who are known to have ingested a contaminated food, it may be prudent to administer treatment or prophylaxis with a course of oral amoxicillin or trimethoprim-sulfamethoxazole.¹⁰³

PROGNOSIS

Maternal listeriosis may result in abortion, stillbirth, or early neonatal death.⁸⁰ Although the relative risk for fetal death is difficult to estimate, spontaneous abortion rates of 10% to 20% and stillborn rates of 11% have been noted.⁸⁰ Fetal distress and/or meconium staining of amniotic fluid is estimated to occur in 75% of perinatal cases.⁸⁰ Convincing evidence that *L. monocytogenes* is associated with repeated abortions is lacking.⁵²

Among cases of early-onset sepsis, the mortality rate in North America is approximately 40% (see Table 95.1).^{1,39} Most survivors appear normal at short-term follow up.^{38,39,142} Sequelae are related to the associated complications of prematurity, pneumonia, and sepsis; hydrocephalus and cerebral palsy also have been reported.^{38,68} Early treatment of maternal disease affects fetal and neonatal outcome favorably.^{39,68}

Late-onset *Listeria* meningitis has a mortality rate of less than 10%. The outcome after *Listeria* meningitis may be more favorable than the outcome associated with other types of bacterial meningitis.^{71,153} Major sequelae are hydrocephalus and mental retardation. Beyond the neonatal period, the outcome of listeriosis depends on the nature of any underlying disease and the availability of intensive medical care. Among adults with no underlying malignancy, the long-term outcome of *Listeria* meningitis is excellent.¹¹⁶

PREVENTION

The sporadic nature of the disease in North America emphasized the need for collaborative investigation and reporting of infections by

physicians and veterinarians to public health authorities.^{11,45} In the early 1990s, listeriosis became a notifiable disease in the United States and Canada.^{109,141} Since then, the important role of food in the transmission of sporadic cases has been firmly established.^{130,141} Inspection of food production facilities and dissemination of educational materials may have contributed to a general reduction of outbreaks of listeriosis since then as well.^{5,42,50,141} Strict adherence to regulations for pasteurization of raw milk is important to inactivate the organism.¹⁹ Contamination of food can occur during the preparation and processing of pasteurized milk products and ready-to-eat meat or poultry products. The source of an outbreak is sometimes found by tracking strains of *L. monocytogenes* isolated from a patient's food to the retail sources. Recommendations for individuals at high risk, such as pregnant women and immunocompromised patients, include avoiding soft cheeses and delicatessen meats, and avoiding reheating leftover foods or ready-to-eat foods (e.g., hot dogs).¹⁰⁹ Despite this, many hospitals have failed to implement appropriate food preparation policies.²³ During an outbreak of *Listeria*, prompt investigation and treatment of pregnant women with a febrile "influenza-like" illness have been advocated.^{11,68} Although treatment of symptomatic mothers may prevent perinatal listeriosis, there is no evidence to show that treatment of colonized infants can either eradicate carriage or prevent infection. Standard precautions are recommended when managing patients with listeriosis.

Tuberculosis

96

Andrea T. Cruz • Jeffrey R. Starke

Tuberculosis still ranks as one of the three most important infectious diseases in the world in terms of morbidity and mortality. The disease is recognizable in skeletons from the Stone Age and in mummified corpses from the Egyptian Old Kingdom. Tuberculosis became more widespread in western Europe after the plague years of the Middle Ages, and the epidemic worsened during the era of urbanization and industrialization in the 18th and 19th centuries.¹⁷² With improving socioeconomic conditions, the mortality rate fell to 200 per 100,000 around 1900, and to 26 per 100,000 by 1950, even before the advent of effective chemotherapy. Stress in all its forms—famine, war, rationing, long working hours, child labor, population displacement, crowded living, and working conditions—favors the spread of tuberculosis in humans, whereas years of peace and plenty favor its rapid decline.^{171,508} Improving socioeconomic conditions in the United States resulted in a decline in TB mortality during the early 20th century. The decrease in the Western world in the incidence of tuberculosis was accentuated by the discovery, development, and widespread use of antituberculosis drugs beginning in the late 1940s.

Another important factor leading to the decline of tuberculosis in Western countries was the recognition in the 1920s of the importance of bovine tuberculosis and its successful eradication as a public health problem in the United States by gradual slaughter of infected cattle and almost universal pasteurization of milk.²¹⁶ Although *Mycobacterium bovis* disease now accounts for a small fraction (1% to 2%) of all tuberculosis in the United States,²⁴⁶ it has been implicated in 5% to 10% of cases in children along border regions of the United States.^{139,202}

STAGES: EXPOSURE, INFECTION, AND DISEASE

The pathophysiologic process of tuberculosis is complicated, and the delay between acquisition of infection and manifestation of disease renders certain pathophysiologic events less distinct.¹¹ There are three major stages of tuberculosis: exposure, infection, and disease.⁶¹²

Exposure implies that the child has had significant recent contact with another person who has infectious pulmonary tuberculosis. The contact investigation—examination of individuals close to a person suspected of having tuberculosis by performing a test of infection (tuberculin skin test [TST] or interferon- γ release assay [IGRA]), chest radiograph, and physical examination—is the most important activity in a community to prevent cases of tuberculosis in children.^{14,52,255} The most frequent setting for exposure of a child is the household, but it

can occur in a school, daycare center, or other closed setting.^{148,247} In this stage, the test of infection is negative, the chest radiograph is normal, and the child lacks signs or symptoms of disease. Some exposed children may have inhaled droplet nuclei infected with *M. tuberculosis* and have early infection, but the clinician cannot know it because delayed hypersensitivity to tuberculin—a positive TST response—takes up to 3 months to develop. Children younger than 5 years old or immunocompromised children of any age who are in the exposure stage should be treated to prevent the rapid development of disseminated or meningeal tuberculosis, which can occur before the test of infection becomes positive.^{179,363,452,487,629}

Infection occurs when the individual inhales droplet nuclei containing *M. tuberculosis*, which becomes established intracellularly within the lung and associated lymphoid tissue. The hallmark of tuberculosis infection is a reactive TST or a positive interferon gamma release assay (IGRA). In this stage, the child has no signs or symptoms and the chest radiograph is either normal or reveals only granuloma or calcifications in the lung parenchyma, regional lymph nodes, or both. In industrialized countries, virtually all children with tuberculosis infection should receive treatment to prevent the development of disease.

Disease occurs when signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. The word *tuberculosis* refers to disease. Not all infected individuals have the same risk for contracting disease. An immunocompetent adult with untreated tuberculosis infection has a 5% to 10% lifetime risk for development of disease; half the risk exists in the first 2 to 3 years after infection occurs. Adults with tuberculosis infection who then become infected with human immunodeficiency virus (HIV) have a 5% to 10% annual risk for development of tuberculosis disease.⁵⁶¹ Historical studies have shown that often serious, life-threatening forms of the disease will develop within a year in as many as 40% of immunocompetent infants with untreated tuberculosis infection.³⁸⁵

EPIDEMIOLOGY

Incidence and Prevalence

Between 20% and 45% of the world's population (approximately 2 billion people) are infected with *M. tuberculosis*, and more than 90% of new cases occur in the developing world. The World Health Organization (WHO) estimates that 9.6 million incident cases, 12 million prevalent cases, and 1.5 million deaths from tuberculosis occur annually

worldwide.⁷¹⁴ Twelve percent of all persons with tuberculosis are HIV coinfecting, but this percentage is as high as 40% in sub-Saharan Africa. True rates of HIV and tuberculosis coinfection are unclear, because many nations do not screen all newly diagnosed tuberculosis patients for HIV.

According to the WHO, in 1997, only 32% of the world's population lived in areas where effective tuberculosis control programs were fully operational⁴⁴⁸; this situation has not improved in the subsequent two decades. Poor tuberculosis control selects for drug-resistant isolates. Multidrug-resistant tuberculosis (MDR-TB), in which the isolate is resistant to at least isoniazid and rifampin, and extensively drug-resistant tuberculosis (XDR-TB),⁵⁶⁹ with resistance to isoniazid, rifampin, non-streptomycin injectable drugs, and fluoroquinolones, have become important problems in many areas of the world.¹⁷⁸ MDR-TB was not described until 1990⁸⁷ but has spread widely. In adults, drug resistance in *M. tuberculosis* often is secondary, with the resistance emerging during therapy because treatment is inadequate or interrupted.¹⁹⁹ In children, drug resistance usually is primary in that the child is infected with a strain that already has become resistant.^{451,542,544,644} Rates of drug resistance in children tend to mirror those in adults in the same population.^{618,619} and may be higher in developing countries because of difficulty in completing therapy and an inadequate supply of child-friendly medication formulations. Three percent of new and 20% of retreatment tuberculosis cases globally (300,000 estimated MDR-TB cases in 2014)⁷¹⁴ are MDR-TB; 54% of MDR-TB cases occur in India, China, and the Russian Federation.⁷¹⁴ The true rates of drug-resistant tuberculosis are unclear. Limitations to accurate estimates include variation in laboratory capacity and reporting, and selection of particular patients for drug susceptibility testing (e.g., patients who are failing standard therapy). Additionally, not all patients have culture-confirmed tuberculosis. Finally, the manner in which rates are reported is important. Although incident cases are a better marker of spread of strains in the community, prevalence rates provide a better reflection of the chronicity of MDR-TB and XDR-TB.

Estimates for children are less accurate for many reasons. In developing countries where the burden of disease is greatest, the only available diagnostic test often is an acid-fast smear of sputum, the result of which rarely is positive from infants and children with pulmonary tuberculosis. This leads to underestimation of the pediatric tuberculosis disease burden. Up to 11% of deaths from adolescence to early adulthood are attributable to tuberculosis and HIV infection/AIDS in high-prevalence areas.⁴⁸³ In areas with both accurate reporting and high rates of tuberculosis, it is thought that children younger than 15 years of age comprise 15% to 20% of the disease burden.³⁸⁹ This figure varies widely among countries: although only 6% of all cases in the United States occur in children,⁹⁸ children are reported to account for 1.4% (Nigeria) to 17% (Swaziland) of cases in sub-Saharan African nations.⁷¹⁵ Some of this variation is real but some likely is due to underreporting and underdiagnosis.

More recent mathematical models have provided more accurate estimates for the 22 high-burden countries (HBCs). In these HBCs, it was estimated that over 15 million children had household contact to a person with infectious tuberculosis, resulting in 7.5 million cases of infection and 650,000 cases of disease annually. The authors estimated that only 35% of all pediatric TB cases were reported.¹⁵⁴ A different group of investigators evaluated the global burden of MDR-TB in children, estimating almost 1 million cases of disease, of which almost 32,000 were MDR-TB.²⁸³ Using similar modeling approaches, in 2015 WHO increased its annual estimates of childhood tuberculosis to 1 million cases and 140,000 deaths annually.⁷¹⁴ In addition, it has been estimated that 9.7 million children had been orphaned as of 2009 after at least one of their parents died of tuberculosis.

The situation in the United States is markedly different. Declining incidence preceded the advent of effective TB treatment and likely reflected improved health status for the American populace. The United States became a low-incidence nation (incidence rate <20/100,000) in the late 1960s. Between 1985 and 1992 in the United States, the total tuberculosis case numbers rose 20%.⁹¹ During that same time, the number of pediatric tuberculosis cases rose 40%.^{284,668} Most experts cite four probable causes for the increases: (1) the co-epidemic of HIV

infection; (2) the increasing rates of tuberculosis in foreign-born individuals in the United States⁷³; (3) the increased transmission among adults in congregate settings, including jails and prisons, nursing homes, homeless shelters, HIV treatment facilities, hospitals, and, rarely, schools^{36,39,54,409}; and (4) a decline in the public health infrastructure in many areas of the country.^{67,117,509,613} After several years of intense and expensive effort were expended, the number of tuberculosis cases in the United States declined again.⁴³⁸

In 2015, a total of 9563 incident tuberculosis cases (three cases per 100,000 population) were reported in the United States.⁹⁸ Six percent of cases occurred in HIV-coinfecting persons. MDR-TB is uncommon in the U.S., accounting for 1.3% of all isolates, with 90% occurring in foreign-born persons. Tuberculosis remains concentrated in certain high-risk groups⁹² (Box 96.1) and regions in the United States (Fig. 96.1). Four states—California, Florida, New York, and Texas—accounted for one-half of all U.S. tuberculosis cases in 2015.⁹⁸ These states are characterized by high numbers of immigrants and ethnic and

BOX 96.1 High-Risk Groups for Tuberculosis Infection and Disease

Groups at High Risk for Exposure or Infection

Close contacts of person with tuberculosis
Foreign-born persons from high-risk countries (Asia, Africa, Latin America, Russia, Eastern Europe)
Residents and employees of high-risk congregate settings (correctional institutions, nursing homes, homeless shelters, hospitals serving high-risk populations, drug treatment centers)
Medically underserved, low-income populations
High-risk racial or ethnic minority populations
Injection drug users
Children exposed to adults in high-risk categories

Groups at Higher Risk for Disease Once Infected

Immunosuppressed patients, including those HIV infected
Recent tuberculosis infection (within past 2 years)
Persons with certain medical conditions (diabetes mellitus, silicosis, cancer, end-stage renal disease, gastrectomy, body weight ≤90% of ideal)
Injection drug users
History of inadequately treated tuberculosis
Children age ≤4 years, especially infants

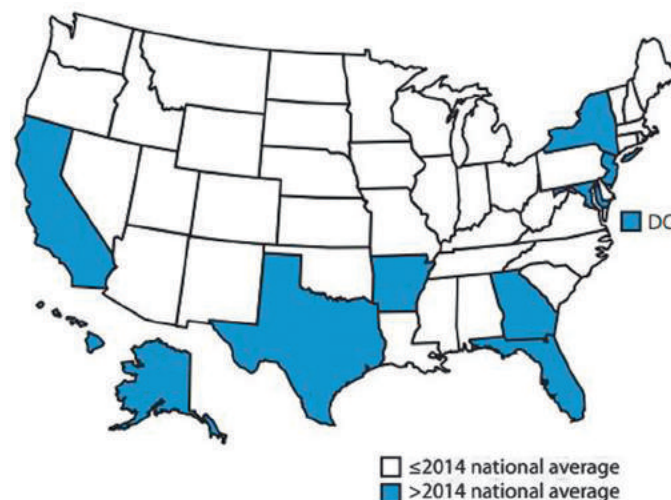

FIG. 96.1 Tuberculosis case rates (cases per 100,000) by state, 2014. (From Centers for Disease Control and Prevention. Tuberculosis trends—United States, 2014. *MMWR* 2015;64:265-9.)

minority group members. In 2015, when compared with U.S.-born non-Hispanic whites, tuberculosis rates among U.S.-born Hispanics, non-Hispanic blacks, and Asians were 2.8, 5.7, and 2.8 times greater, respectively.⁹⁸

Sixty-seven percent of all U.S. TB cases occur in foreign-born persons; over half of cases are from persons born in Mexico, the Philippines, Vietnam, India, and China. This trend reflects several themes: declining rates of TB in U.S.-born persons; failure to screen and/or treat adult immigrants for infection; high prevalence of TB infection and disease in these nations; and limited access to care after arrival in the United States. During the immigration process, adults are screened for tuberculosis disease with a chest radiograph, but testing to detect tuberculosis infection is not required. In 2009, the United States began requiring tests of infection for children 2 to 14 years old prior to immigration but not treatment for a positive test.⁹⁶ Before this, children emigrating to the United States were entirely unscreened for TB. Tuberculosis is endemic in most developing countries, and between 30% and 50% of recent immigrants to the United States have tuberculosis infection before entry into the country.^{113,639} Foreign-born adopted children also are at risk for having tuberculosis infection and disease.^{198,334,526} People who enter the United States without documentation may be unable or afraid to seek medical treatment, even when they are ill. Studies have shown that in most immigrants in whom tuberculosis develops, it does so within 5 years of immigration, thus indicating that many cases could be prevented if appropriate screening and treatment programs were conducted.

Other important risk factors for tuberculosis in adults include lower socioeconomic status, migrant work, HIV infection, drug use, homelessness, travel to high-prevalence countries, history of incarceration, and occupations with exposure to high-risk populations (Box 96.1). Children from high-risk population groups or children who have contact with adults in these groups may be at increased risk for tuberculosis infection.³⁶¹ Age has an important influence on tuberculosis case rates.⁴⁴² During 2014, 6% of cases in the United States occurred in children younger than 15 years, 11% in persons 15 to 24 years old, 33% in persons 25 to 44 years old, 31% in persons 45 to 64 years old, and 20% in persons older than 64 years.⁹⁸ The highest case rates among children are in those younger than 3 years. Children aged 5 to 14 years, the so-called favored age, have a consistently lower case rate than that of any other segment of the population.^{384,442} In early childhood, the incidence is not significantly different in girls and boys, although higher rates of disease are generally experienced by adolescent girls than adolescent boys.⁶²

An estimated 4% to 6% of the U.S. population, or approximately 13 million people, are infected with *M. tuberculosis*.²⁵² The percentage of infected people varies widely by racial and ethnic groups and socioeconomic status. Foreign-born persons residing in the United States have a prevalence of infection of 19%. Among African-Americans the prevalence is 7%; Mexican-Americans, 9%; and persons living in poverty, 6%.⁴¹ This group of infected persons represents a large reservoir from which cases of tuberculosis disease will emerge in the future if these individuals are not treated.⁷

The HIV epidemic has had a profound effect on the epidemiology of tuberculosis in children by two mechanisms⁵³⁷: (1) most important in the United States, HIV-infected adults with tuberculosis may transmit *M. tuberculosis* to children in their environment and tuberculosis disease will develop in some of them³¹⁵; and (2) important in many developing countries, children with HIV infection are at increased risk for progressing from asymptomatic tuberculosis infection to disease.^{265,366} Several studies have demonstrated increased rates of childhood tuberculosis associated with increased rates of disease among HIV-infected adults in the community.^{232,288} Tuberculosis probably is underdiagnosed in HIV-infected children, especially in the developing world, because of the similarity of its clinical manifestations with other opportunistic pulmonary diseases and the difficulty of confirming the diagnosis with the skin test or culture. All children with suspected tuberculosis disease should have HIV serotesting because the two infections are linked epidemiologically and many experts prolong treatment in HIV-infected children with tuberculosis.^{226,545,701}

Children comprise a small fraction of tuberculosis cases in the United States, in part because of low rates of coinfection with HIV, an older

FIG. 96.2 Extrapulmonary disease by site in adults and children in the United States. (From the Centers for Disease Control and Prevention.)

population structure than many developing nations, and far less recent transmission. The site of manifestation of tuberculosis disease differs between adults and children. Although pulmonary disease is most common for all ages, extrapulmonary tuberculosis occurs more often in children.⁴⁴² In general, 25% of pediatric cases are extrapulmonary, with 75% being pulmonary. In 1985, before widespread HIV infection occurred, 85% of adults had pulmonary disease and 15% had extrapulmonary disease. With the spread of HIV infection, these numbers have shifted; and in recent years, the Centers for Disease Control (CDC) reported that 79% of all new cases, including those in adults and children, were pulmonary and 21% were extrapulmonary. Comparison of the site of extrapulmonary disease in children and adults in 1985, before the AIDS epidemic, shows some important differences. First, approximately 70% of extrapulmonary tuberculosis in children involved the lymph nodes, as opposed to 25% in adults (Fig. 96.2). Second, tuberculous meningitis accounted for 13% of extrapulmonary disease in children versus 4% in adults. Genitourinary involvement occurred in 16% of adults, but it was a rare finding in children. Although the proportion of extrapulmonary cases in adults has increased as a result of the HIV-AIDS epidemic, extrapulmonary disease still occurs more commonly in children.

TRANSMISSION

Transmission of tuberculosis is from one human to another, usually through infected droplets of mucus that become airborne when an individual coughs, sneezes, or laughs.¹⁰⁸ The droplets dry and become droplet nuclei, which may remain suspended in air for hours. Only particles less than 10 μm in diameter are small enough to reach the alveoli.⁵³⁸ Transmission sometimes occurs by direct contact with infected discharges (sputum, saliva, urine, or drainage from an open sinus or abscess); it occasionally occurs by means of heavily contaminated fomites, such as gastric lavage tubes, bronchoscopes, or syringes prepared by

someone with positive sputum.²⁴⁴ Rare cases of tuberculosis transmitted by a lung or kidney transplant have been reported.^{93,437} Dogs, pigs, goats, and camelids (camels, llamas, alpacas) can play a role in interspecies transmission of *M. tuberculosis* complex.⁴⁹⁶ One necropsy study showed that the prevalence of tuberculosis disease and infection in dogs in a high-prevalence setting (South Africa) was 1% and 50%, respectively.⁴⁸¹

The proxy for contagiousness historically has been acid-fast sputum smear microscopy. Conversion of sputum smears from positive to negative after starting treatment has been used as an indication that a patient is no longer contagious. However, some patients with prolonged sputum smear positivity have few or no close contacts who become infected, whereas other patients with negative sputum smears have many infected contacts. One explanation for this phenomenon may be that not all patients aerosolize viable bacteria. A recent study found that the density of cough-generated aerosols correlated more with TST and IGRA positivity in contacts than the degree of sputum smear positivity. Even among sputum smear-positive adults, only 30% produced cough-generated aerosols.²⁸⁹

The collective experience of many clinicians is that children usually are infected by an adult or adolescent in the immediate household, most often a parent, grandparent, older sibling, boarder, or household employee.³⁸ It is estimated that 1% to 5% of household contacts of a person with TB will also have disease.⁷¹⁹ Casual extrafamilial contact is the source of infection much less often, but physicians, babysitters, schoolteachers, music teachers, school bus drivers, parishioners, nurses, gardeners, and candy store keepers have been implicated in individual cases and in hundreds of mini-epidemics.^{23,60,174,340,348,695} Attention has been drawn to the prevalence of active tuberculosis among residents of nursing homes for the elderly.²⁶⁸ Children visiting their grandparents have contracted tuberculosis in this setting. Within the household of an infectious adult, infants and toddlers most often become infected. Adults with pulmonary disease who are receiving regular, appropriate chemotherapy probably rarely infect children; much more dangerous are those with chronic tuberculous disease that is unrecognized, inadequately treated, or in relapse because of the development of resistance. Modeling studies suggest that increasing case detection by 25% can result in an almost 50% reduction in TB mortality and an almost 30% reduction in TB incidence.⁷¹⁹

Wallgren⁶⁸⁸ was the first to point out that children with tuberculosis rarely infect other children. Many children with the disease have tuberculin-negative siblings and parents. Children with tuberculosis often have been cared for by their families or in hospitals and institutions without infecting their contacts.^{126,436} When transmission of *M. tuberculosis* has been documented in children's hospitals, it almost invariably has come from an adult with undiagnosed pulmonary tuberculosis.^{24,294,295,425,697} Adults accompanying a child with suspected tuberculosis disease should be screened as soon as possible for pulmonary tuberculosis.^{63,95,112,126,296,297,436,608} In tuberculous children, tubercle bacilli in endobronchial secretions are relatively sparse and cough is not characteristic of endothoracic tuberculosis or miliary disease. When young children cough, they lack the tussive force of adults. Specimens collected by bronchoalveolar lavage or early-morning gastric aspiration from children with clinically suspected tuberculosis seldom have acid-fast bacilli seen on smears. Only approximately 40% eventually will grow *M. tuberculosis* by culture.⁵⁹⁷ Young infants with congenital tuberculosis or advanced, postnatally acquired pulmonary disease are more likely to have smear- or culture-positive specimens (80%) than older children.^{541,669} Therefore, specimens and secretions from infants, children with cavitary lesions, and intubated patients should be handled as potentially infectious.^{95,397} Most preadolescent children with tuberculosis, however, are not contagious and do not require isolation. Tuberculosis in adolescents may be more typical of adult-type reactivation disease, including the presence of cavitary lesions with smear- and culture-positive sputum. Children or adolescents who have symptomatic pulmonary tuberculosis with features of adult-type tuberculosis should be treated as potentially contagious until mycobacterial smears and cultures are negative.^{77,133}

Children, nonetheless, play an extremely important role in the transmission of tuberculosis, not so much because they are likely to

contaminate their immediate environment, but rather because they may harbor a partially healed infection that lies dormant, only to be reactivated as infectious pulmonary tuberculosis many years later under the social, emotional, and physiologic stresses arising during adolescence, pregnancy, or old age. Thus, children infected with *M. tuberculosis* constitute a long-lasting reservoir of tuberculosis in the population. From an epidemiologic perspective, the diagnosis of tuberculosis disease in a child is a marker of recent transmission in the community, owing to the short incubation periods seen for childhood tuberculosis.

The risk for infection developing in child contacts of adults receiving antituberculosis chemotherapy often is a matter of practical concern. Several studies reveal that most contacts are infected by the index case before the diagnosis is made and treatment is initiated. Although it is not possible to carry out a definitive clinical study, evidence indicates that patients receiving effective chemotherapy rarely transmit *M. tuberculosis*. Nonetheless, it seems prudent to avoid exposure of children to adults with positive sputum smears or positive cultures and to assume that adults positive by smear or culture remain infectious for at least several weeks after the start of therapy.

MYCOBACTERIOLOGY

The genus *Mycobacterium*, closely related by its cell wall antigens to the genera *Corynebacterium* and *Nocardia*, is classified in the order Actinomycetales and the family Mycobacteriaceae. Several species are termed *M. tuberculosis* complex (MTBC): *M. tuberculosis*, *M. africanum*, *M. bovis*, *M. canetti*, and *M. microti*. Phylogenetic analysis indicates an origin for MTBC approximately 40,000 years ago, coinciding with expansion of humans out of eastern Africa.⁷⁰⁶

Mycobacteria are nonmotile, non-spore-forming, pleomorphic, weakly gram-positive rods measuring 1 to 5 μm long and typically slender and slightly "bent." Some appear beaded, and some are clumped. The cell wall constituents of mycobacteria determine their most striking biologic properties. The cell walls contain 20% to 60% lipids by dry weight, largely bound to proteins and carbohydrates. These organisms are more resistant than are most others to light, alkali, acid, and the bactericidal action of antibodies. Their growth is slow, with a generation time of 14 to 24 hours, perhaps because of the slow metabolic exchange through the waxy "capsule." Their hydrophobic properties render them difficult to study.

Acid-fastness, that is, the capacity to form stable mycolate complexes with certain aryl methane dyes (specifically, carbolfuchsin, crystal violet, auramine, and rhodamine, which then are not removed readily even by rinsing with 95% ethanol plus hydrochloric acid), is the hallmark of mycobacteria. The cells appear red when stained with fuchsin (as with the Ziehl-Neelsen or Kinyoun stains), appear purple with crystal violet, or exhibit yellow-green fluorescence under ultraviolet light (when stained with auramine and rhodamine, as in Truant stain). Truant stain, in experienced hands, is considered the best stain for specimens expected to contain small numbers of organisms. Fluorescent staining can decrease staining time by 50% and increase sensitivity capacity in high-volume laboratories in developing countries when compared with Ziehl-Neelsen staining.³⁴¹ One study of LED fluorescence microscopy in adults showed that fluorescence microscopy was more sensitive but less specific than Ziehl-Neelsen staining, in part because in the fluorescence microscopy artifacts can fluoresce, leading to false-positive results.¹³⁰

Identification of mycobacteria depends on their staining properties and on their biochemical and metabolic characteristics. Mycobacteria are obligate aerobes. On the whole, their growth requirements are simple. *M. tuberculosis* can grow in "classic" media, whose essential ingredients are egg yolk and glycerol (Löwenstein-Jensen, Petragani, Dorset). These media often include a dye, such as malachite green, to inhibit contaminants or potatoes and charcoal, which probably neutralize growth inhibitors. They also can grow in synthetic media, frequently with an admixture of asparagine, glutamate, or amino acid mixtures (Middlebrook 7H9, Tween-albumin). Once grown, they can be replated on media also containing antituberculosis drugs to determine drug susceptibility patterns. Isolation on solid media often takes 3 to 6 weeks, followed by another 2 to 4 weeks for drug susceptibility results. Improvements in laboratory methods have permitted more rapid culture,

identification, and drug susceptibility testing of mycobacteria, such as by an automatic radiometric method known as the BACTEC method, in which a decontaminated, concentrated specimen is inoculated into a bottle of medium containing carbon 14-labeled palmitic acid as the substrate.⁵⁷⁷ As mycobacteria metabolize the carbon 14-labeled palmitic acid, carbon dioxide 14 accumulates in the head space of the bottle, where radioactivity can be measured. Unfortunately, cross-contamination of bottles has been reported and has resulted in false-positive culture results.¹⁷³ The addition of appropriate dilutions of antituberculosis drugs permits an evaluation of drug susceptibility to be made. The time for identification and drug susceptibility testing can be reduced to 1 to 3 weeks, depending on the size of the inoculum.

Restriction fragment length polymorphism (RFLP) analysis and whole-genome analysis of mycobacterial DNA have become powerful tools for determining strain relatedness in both outbreaks and routine epidemiology of tuberculosis in a community, allowing for social network analysis.^{9,206,582,710}

RESISTANCE AND IMMUNITY

Natural resistance to tuberculosis infection varies greatly among animal species; humans, guinea pigs, and rabbits are highly susceptible. Multiple single nucleotide polymorphisms (SNPs) have been associated with disease susceptibility in a number of racial and ethnic groups: *CCL2-2518G* in Asians and Latinos,¹⁹⁴ *IRGM*³¹² and interleukin-12B in African-Americans, and *P2X7* and Toll-like receptor 2 and 8 mutations in Turkish children.^{134,135,645} However, few mutations, apart from *SLC11A1*,³⁴⁵ have been identified that appear to increase susceptibility across racial and ethnic groups. Many of these mutations are in genes influencing macrophage-mediated destruction of the bacillus.^{312,645} Other risk factors for the development of TB disease include young age,^{442,540,669} poorly controlled diabetes mellitus,⁶⁹⁶ and wild-type measles and perhaps influenza.^{40,238,730} Unfortunately, natural resistance is ill defined and poorly understood.

Cell-mediated immunity is regarded as most important in host defense against *M. tuberculosis*.^{164,344} The T cell-mediated immune response involves a variety of cell subsets that are involved in numerous functions, including protection, delayed hypersensitivity, cytotoxicity, and establishment of memory immunity.⁴⁶⁸ The functions also involve an array of cytokines, several of which direct cells of the monocyte-macrophage axis to contain and destroy the invading bacilli.^{15,635} An emerging concept is that much of the clinical response to the presence of *M. tuberculosis* is determined by the balance of the cellular cytokine response,¹⁶⁴ which to some degree is under genetic influence.⁴⁶⁸ In general, T-helper 1 (Th1) responses are more beneficial to the host than are Th2 responses, in part owing to the former's role in activating macrophages in granulomas.¹⁶⁴ Unfortunately, infants and young children have increased propensity to develop Th2 responses to mycobacterial immunogens.³⁴⁴ Although different strains of *M. tuberculosis* can evoke different host immune responses, there is no apparent association between the genotype and the phenotype expressed in children with disease.³⁹¹

More details about the immune response to *M. tuberculosis* are emerging as new immunotherapies are developed. During the past decade, several monoclonal antibodies directed against tumor necrosis factor- α have been used to manage inflammatory bowel disease and rheumatologic disorders. Unfortunately, use of these agents, particularly infliximab, has been associated with up to a 25-fold increased risk for tuberculosis disease.⁵⁹⁶ All immunocompromised patients, including those who will undergo any form of immunotherapy, should be evaluated carefully for tuberculosis infection or disease.

PATHOGENESIS

Portal of Entry

The tubercle bacillus usually is inhaled. The observations of Riley⁵¹⁷ suggest that a single tubercle bacillus can initiate infection. Ghon, Kuedlich, and their associates (Table 96.1) reported that the primary focus found in 2114 autopsies on children was the lung in 96% of cases. Especially significant is that their study was done at a time when bovine tuberculosis, which might have produced many primary gastrointestinal

foci, was much more common than it is today. Ingestion probably accounts for a small percentage of primary pulmonary foci and for some gastrointestinal foci, particularly in infants who have consumed milk containing bovine tubercle bacilli. *M. tuberculosis* has also been transmitted by organ transplantation.⁹³ Contamination of marijuana bongs has been associated both with clusters of pulmonary tuberculosis⁴³⁵ and uvulitis.²²⁴ Contamination of a superficial skin or mucous membrane lesion, such as an abrasion of the sole of the foot or the elbow, insect bite, ritual circumcision, or infection of the vulva, may lead to infection. Infection by inoculation with a sputum-contaminated syringe has been reported in more recent years.²⁴⁴ True congenital infection, although rare, may be a result of either lymphohematogenous spread in the mother during pregnancy or smoldering endometritis.⁶⁷¹

Incubation Period

The incubation period from the time that the tubercle bacillus enters the body until cutaneous sensitivity develops has been found to be 3 weeks to 3 months.³⁸⁵ With both bacille Calmette-Guérin (BCG) and experimental infections, the incubation period is shorter and the clinical manifestations are more severe when the inoculum is large; clinical experience suggests that the same is true in humans. Debré, for example, noted long ago that tuberculosis acquired by an infant from its mother was likely to be much more severe than was an infection acquired from a visitor to the home.¹⁴⁴

"Timetable" of Tuberculosis

Wallgren's tremendous experience with tuberculous children in institutions permitted him to recognize and describe the usual early course and timing of the initial infection and each of its best-known complications.⁶⁹¹ His timetable concept is an extremely useful one for clinicians because it permits a realistic prognosis, an understanding of what complications to look for and when, and a more productive approach to finding the infectious source case (Fig. 96.3).³⁸⁵ Half of the lifetime risk of progression to disease occurs within 2 years of infection.⁵⁷

The relationship between the anatomic site of tuberculosis and the median age at onset in children is shown in Table 96.2. Symptomatic, massive lymphohematogenous spread (i.e., miliary or acute meningeal tuberculosis) is seen in only 0.5% to 3% of infected children. When it does occur, the usual onset is 2 to 6 months after initial infection. Endobronchial tuberculosis, possibly with segmental pulmonary lesions, develops slightly later on average. The metastatic lesions of bones and joints, which can be expected in 5% of untreated infected children, usually do not appear until approximately 1 year after infection occurs, at the earliest. Renal lesions come later still, 5 to 25 years after initial infection. The interval between the acquisition of initial infection and the appearance of chronic pulmonary tuberculosis is extremely variable but can be months to decades, depending mainly on the age of the child at the time of infection. The interval is likely to be short in adolescents but much longer in infants.

In summary, the first 5 years after initial acquisition of tuberculosis infection in childhood, especially the first year, is when complications usually occur. Later in life, during times of stress, a previously silent or arrested lesion may reactivate and become dangerous to the patient as well as highly infectious to others.

CLINICAL FORMS OF TUBERCULOSIS IN CHILDREN

Endothoracic Asymptomatic Tuberculosis Infection

Asymptomatic (or latent) infection can be defined as tuberculin hypersensitivity and a positive tuberculin test result without striking clinical or radiographic manifestations. Computed tomography (CT)—which is not recommended in the routine evaluation for pulmonary TB in children—may reveal enlarged lymph nodes in the chest, even though the plain radiograph is normal.^{17,146} On occasion, low-grade fever is found at the onset, usually by chance. If the child has been in recent contact with a person who has contagious tuberculosis and the TST result is positive, disease should be ruled out immediately with a

chest radiograph and a thorough physical examination. The lifetime risk of progression from infection to disease is lowest for elementary school-aged children (<5%), intermediate for adolescents and preschool-aged children (10–20%), and highest for infants (40–50%).⁴⁸⁵

A clinician making a diagnosis of tuberculosis infection in a child must assume that the patient might be in the earliest stage of infection and at risk for the development of symptomatic disease in the near future.³⁸⁵ A careful history and investigation of contacts should be undertaken immediately for determination, if possible, of the date of exposure. Chemotherapy must be started, and the patient closely monitored not only to detect any toxic effect of chemotherapy and to monitor adherence with treatment, but also to be sure that disease does not develop.

Endothoracic Primary Complex and Its Complications

The primary complex, described by Ghon,²⁰⁹ includes three elements: the primary focus, lymphangitis, and regional lymphadenitis. This complex holds true for every primary infection, regardless of the portal of entry. Ghon noted that at least 70% of primary pulmonary foci are subpleural. Thus, pleurisy is almost a regular feature of the primary complex. Evolution of the primary pulmonary focus begins with an acute inflammatory reaction around tubercle bacilli inhaled into an alveolus, with the localized alveolar consolidation varying from the size of a pea to the size of a walnut. Macrophages appear within hours in the inflammatory exudate and change into clusters of epithelioid cells to form tubercles. In turn, these tubercles may resolve and disappear, or central caseation consisting of incomplete cell autolysis may develop. The caseous lesion contains large numbers of multiplying tubercle bacilli that spread rapidly from the primary focus through the regional lymphatic vessels to the regional lymph nodes, with areas of inflammation being set up along the way that later may caseate and calcify.⁴⁹⁷ The primary pulmonary focus (Table 96.3) can be located in any part of the lung. The thought that the primary focus has a predilection for the lower fields of the lung probably arises from the fact that the lung is pyramid shaped, with more basilar than apical lung tissue. Seventy to

Based on data of Rouviere, cited in Courtice FC, Simmonds WJ. Physiological significance of lymph drainage of the serous cavities and lungs. *Physiol Rev*. 1954;34:419–42.

85% of primary infections are initiated by one focus.⁶³⁶ Multiple lung foci can result, although rarely, from the ingestion and inhalation of tubercle bacilli. This pattern of disease was shown clearly in the results of pathologic studies of the 71 infants who died in the Lübeck disaster of the 1930s, an incident in which 251 neonates mistakenly had been given live tubercle bacilli by mouth instead of BCG vaccine. Fifteen of the neonates were found to have primary lung lesions at autopsy, and all 251 had primary intestinal lesions.

Although the lymphadenitis cannot be detected clinically and rarely is apparent even on radiographs, the hallmark of initial tuberculosis infection is the relatively large size and importance of the adenitis as opposed to the relatively insignificant size of the initial focus in the lung, skin, or elsewhere. The development of tuberculin hypersensitivity within 3 to 12 weeks after initial acquisition of infection enhances the cellular reaction throughout the primary complex, but with a particularly prominent effect on the primary focus and the regional lymph nodes. At this time, the infection may spread along nearby lymphatic chains to involve more distant nodes. The lymphatic drainage of the lungs is outlined in Table 96.4; it occurs predominantly from left to right. It is not surprising, therefore, that the nodes in the right upper paratracheal area appear to be the ones most often affected. Many primary lesions are subpleural, and the lymphatic drainage of the apical pleura is to the cervical nodes. Moreover, the paratracheal chains have communications with both the deep cervical nodes and the abdominal nodes, as shown in Fig. 96.4. Calcification of regional lymph nodes is a late finding, usually seen after at least 2 to 6 months.

Extrinsic bronchial obstruction can result from enlargement of peribronchial lymph nodes.^{351,354,604} Clinically, bronchial obstruction can result in one of three outcomes: sudden death from asphyxiation (very rare),³³¹ hyperaeration, or atelectasis. At the end of the incubation period, as tuberculin sensitivity develops, the hilar lymph nodes enlarge greatly and, in many cases, caseous foci appear within them. Acid-fast studies of smears and sections have confirmed that this caseum has few tubercle bacilli. As the nodes enlarge, they frequently impinge on the neighboring regional bronchus and compress it and cause diffuse inflammation of its wall, even to the point of obstructing the lumen.^{351,354,604} Other mechanisms of obstruction include damage to the bronchial cartilage leading to gradual (or, rarely, abrupt) perforation of the bronchus and the formation of plugs of semiliquid toothpaste-like caseum that partially or completely occludes the bronchus. In some

FIG. 96.4. Composite image illustrating wide lymphogenic spread of tuberculosis infection from a primary pulmonary focus in the base of the left upper lobe. The infection extends cephalad to the submandibular nodes in the head and caudad as far as the pancreatic nodes in the abdomen. (From Caffey J. *Pediatric x-ray diagnosis*. 7th ed. Chicago: Year Book; 1978.)

cases, endobronchial granulomatous tissue forms around the stoma of the fistula and obstructs the lumen.

Obstructive hyperaeration (also called *obstructive emphysema*) can involve a lobar segment, a lobe, or even an entire lung. Hyperaeration is most common in children younger than 2 years old. Physical examination can demonstrate wheezing that is not relieved by beta agonists. Radiographs, best taken on expiration, show hyperaeration, which usually is not accompanied by mediastinal displacement, probably because of fixation by the tuberculous mediastinal nodes (Fig. 96.5). Aspiration of a foreign body always must be considered in the differential diagnosis. The obstruction ultimately resolves by itself; however, corticosteroids may be added to the chemotherapeutic regimen to hasten recovery.^{443,444,659} Surgical removal of the obstructing nodes has been successful but rarely is performed.¹⁴²

The third possible result of bronchial obstruction is the appearance of a segmental lesion (termed *collapse-consolidation lesion*) that is fan-shaped on a radiograph, representing mainly atelectasis and almost always involving the very segment occupied by the primary pulmonary focus.^{328,383,427} (Fig. 96.6). Actually, the radiographic opacity results from a combination of several elements: the primary pulmonary focus, the caseous material from an eroded bronchus, the inflammatory response elicited by the caseum, and atelectasis. In some instances, acute secondary infection plays a role. Children with secondary bacterial pneumonia often initially have high fever, cough, and rales; the signs and symptoms respond to conventional antibiotics, but the chest radiographic findings usually do not clear because of the underlying tuberculosis. The younger the child, the more frequently collapse-consolidation lesions occur (Table 96.5). The segmental lesion is likely to form during the first 3 to 6 months after acquisition of infection (50 of 65 in Payne's series⁴⁸⁵) and multiple segmental lesions can occur simultaneously. Sometimes, segmental lesions and obstructive hyperaeration occur simultaneously. The physical signs and symptoms of segmental lesions—cough, rales, localized wheezing, egophony—are surprisingly meager but are seen more frequently in infants because of the smaller size of their airways.

Although segmental lesions and hyperaeration are the most common findings produced by enlarging thoracic lymph nodes, others occur. Enlarged paratracheal nodes may cause stridor and respiratory distress.³⁸² Subcarinal nodes may impinge on the esophagus, causing difficulty

FIG. 96.5. Radiograph of an 8-month-old girl with obstructive hyperaeration of the right lower lobe as a result of tuberculosis. (A) Note the hyperlucent right lower lobe and shift of the heart and mediastinum away from the ball-valve obstruction to the left. (B) Note the large hilar lymph nodes compressing the right lower lobe bronchi. Tuberculosis should be considered in patients with hyperaeration of unknown cause.

6–10	31 (25)	121
11–15	16 (16)	97
Total	159 (29)	545

Based on Payne M, cited in Miller FJW, Seale RME, Taylor MD. *Tuberculosis in children*. Boston: Little, Brown; 1963.

swallowing, or erode into the esophagus, producing a bronchoesophageal fistula. Enlarged lymph nodes may compress the subclavian vein and produce edema of the hand and arm, or they may erode major blood vessels, including the aorta. They also may rupture into the mediastinum and point in the left or more often the right supraclavicular fossa. Compression of the left recurrent laryngeal nerve has been reported. Compression of the left phrenic nerve leads to paralysis of the left leaf of the diaphragm in an estimated 0.1% to 0.3% of tuberculous children. Rupture into the pericardial sac is described later.

The late results of bronchial obstruction include the following possibilities: complete reexpansion of the lung and resolution of the radiographic findings; disappearance of the segmental lesion, with residual calcification of the primary focus or the regional lymph nodes; or scarring and progressive contraction of the lobe or segment, usually associated with bronchiectasis.^{351,385} Permanent anatomic sequelae result

FIG. 96.7. (A) Posteroanterior and (B) lateral radiographs of a 7-year-old boy with a calcified left upper lobe, primary complex. (C) Tomogram showing the fine granular calcific pattern.

from segmental lesions in approximately 60% of all cases, even though the abnormality usually is not apparent on plain radiographs. Fortunately, most of these abnormalities are asymptomatic in the upper lobes. However, secondary infection may occur in the middle and lower lobes and cause the middle lobe syndrome.⁶⁶ On occasion, the chronic vascularity that accompanies bronchiectasis leads to poor oxygen saturation during exercise and to restricted body growth. In addition, bronchogenic carcinoma may arise years later in the old scarred lesions remaining in the bronchus.

Calcification of the primary complex (Fig. 96.7), when it appears, always results from caseation. Calcification of caseous lesions occurs much more readily in children than in adults, probably because children's calcium and phosphorus plasma levels are higher. Payne,⁴⁸⁵ in a study of calcification in 299 English children, reported calcification visible on the chest radiographs of one child within 6 months of infection, 13% within 12 months, 35% within 18 months, 55% within 24 months, 84% within 3 years, and 100% within 4 years.

Calcification may persist without much change, or it may start resorbing within 5 years and eventually disappear completely. Calcification, if it is visible at all on radiographs, most often involves the regional lymph nodes.⁶¹ Sometimes, however, the primary pulmonary focus or the entire primary complex, including the lymphangitis, calcifies (Fig. 96.8). Currently, extensive calcification occurs uncommonly in the Western world, probably because tuberculous lesions treated early with isoniazid rarely caseate and caseation is a prerequisite for calcification.

Pleural Effusion

Pleural effusion (Fig. 96.9) can be localized or generalized and unilateral or bilateral.³⁴⁹ Most children will have concomitant pulmonary parenchymal disease and/or intrathoracic lymphadenopathy.¹²⁷ All tuberculous serous effusions probably originate in the discharge of bacilli into the cavity from an adjacent lesion—in the case of the pleura, from a subpleural pulmonary focus or from subpleural caseous lymph nodes. The breakthrough may be small and the pleuritis localized and asymptomatic, or it may occur in the form of a generalized effusion, usually 3 to 6 months after infection occurs (see Fig. 96.11). In 75% of Wallgren's cases,⁶⁸⁹ later calcification of the pulmonary focus or regional lymph nodes proved the effusion to be on the same side as the original primary focus. Seemingly without logical explanation are the following clinical observations: tuberculous pleural effusion is a rare occurrence in children younger than 2 years and an uncommon one in children younger than 5 years (perhaps because sensitivity to tuberculin is lower in the very young); occurs more frequently in boys than in girls; almost never is associated with a segmental lesion; and rarely is associated with miliary tuberculosis.

The onset of pleurisy usually is abrupt and resembles bacterial pneumonia, with fever, chest pain, shortness of breath, and, on physical

examination, dullness to percussion and diminished breath sounds. Fever may be high and, in untreated cases, last for several weeks. On occasion, differentiation of an effusion from an extensive pneumonic lesion is difficult; lateral decubitus radiographic views are helpful in confirming the presence of pleural fluid.

Thoracentesis is the essential diagnostic procedure. The puncture should be made in the area shown on the radiograph to have the greatest accumulation of fluid. No more than 30 mL of pleural fluid should be withdrawn; otherwise, the protein loss from this usually protein-rich fluid may be considerable. The fluid generally is greenish yellow, occasionally tinged with blood, with a specific gravity of 1.012 to 1.022, a high protein content, and often a low glucose level (<30 mg/dL), and it has several hundred white cells/mm³ with a predominance of neutrophils (early in disease) or lymphocytes, depending on the age of the effusion. Polymerase chain reaction (PCR), adenosine deaminase levels of greater than or equal to 38 IU/L, and absolute lymphocyte count of greater than or equal to 275 cells/mm³ in pleural fluid had a sensitivity and specificity of 74% and 88%, 81% and 75%, and 90% and 83%, respectively, in one study of children with tuberculous effusions.⁴¹⁶ Acid-fast smears almost always are negative, and pleural fluid cultures are positive in less than 30% of cases. Pleural biopsy is a useful diagnostic procedure because both the finding of typical tubercles on histologic study and culture of the tissue are much more likely to establish the diagnosis than is culture of pleural fluid.³⁴³

The prognosis for children with tuberculous effusions always has been relatively good compared with that for other overt forms of tuberculosis, even in the days before chemotherapy.³⁵³ Clinical improvement occurs well before radiographic resolution of disease; the majority of children have radiographic abnormalities at the completion of therapy.¹²⁷ Permanent impairment of pulmonary function is a surprisingly uncommon event after pleural effusion.¹⁹⁷ The development of scoliosis is a remote possibility.

Progressive Pulmonary Tuberculosis

In this serious complication of the primary complex, the primary pulmonary focus, instead of resolving or calcifying, enlarges steadily and develops a large caseous center. This center then liquefies and empties into an adjacent bronchus to create a "primary cavity"^{643,673} (Fig. 96.10); the liquefaction is associated with particularly large numbers of tubercle bacilli. The tubercle bacilli further disseminate to other parts of the lobe and to the entire lung, where other foci of infection form. On rare occasion, an enlarging primary focus ruptures into the pleural cavity and creates a pneumothorax, bronchopleural fistula, or caseous pyopneumothorax or ruptures into the pericardial sac or the mediastinum.

A progressive lesion often is accompanied by more severe fever, cough, malaise, and weight loss, as well as classic signs of cavitation, such as egophony.^{223,541} Before chemotherapy was available, the inability

FIG. 96.8. (A–B) Radiographs of a 7-month-old girl with mild fullness of the right upper mediastinum and a hazy infiltrate in the right lower lobe. The result of a skin test for tuberculosis was positive. She was treated for tuberculosis and clinically improved. (C) The same patient 3.5 years later has a calcified primary complex in the right upper and lower lobes over the diaphragm. (D) The anterior location of the upper lobe complex is seen clearly on the lateral chest radiograph.

FIG. 96.9. (A) Posteroanterior chest radiograph of a 5-year-old boy with massive left pleural effusion caused by tuberculosis. (B) Normal radiograph 6 years later from the same patient who had no physical complaint.

to contain the primary focus was associated with a grave outlook; 25% to 65% of affected patients died. Now, with appropriate treatment, the prognosis is good.

Distinguishing between progressive pulmonary tuberculosis and a simple tuberculous focus with a superimposed acute bacterial pneumonia caused by *Staphylococcus*, *Klebsiella*, or anaerobes may be difficult. Antimicrobial agents effective against these pathogens may be indicated, in addition to appropriate antituberculosis drugs. Sometimes, especially during convalescence from pulmonary parenchymal lesions, bullous lesions appear and persist for several months. They seem to be associated, in children as in adults, either with “tears” in damaged alveolar walls or with the emptying of caseum out of cavities.³⁹⁸

Chronic Pulmonary Tuberculosis

Chronic pulmonary tuberculosis, sometimes referred to as adult or reactivation tuberculosis, is the type of disease seen in pulmonary tissue sensitized and immunized by an earlier tuberculosis infection. Endogenous reinfection is the usual event.⁶¹⁵ However, reinfection with a different strain of *M. tuberculosis* has been documented and may be more common in areas where tuberculosis is prevalent.⁵⁸³

Careful long-term studies of children have revealed a continuum of involvement in many cases: first the primary focus, followed within a few years in some patients by infraclavicular small round foci in the lung apices that often were calcified (Assmann foci, Simon foci) and thought to result from hematogenous spread at the time of initial infection. Later, these foci disappear spontaneously or remain visible as tiny calcifications or as larger “round foci,” which may, if untreated, progress to the typical lesions of chronic pulmonary tuberculosis.

Even before antituberculosis drugs were discovered, chronic pulmonary tuberculosis was a rare occurrence in children (e.g., 6–7% in the series of Lincoln and colleagues³⁵⁰ of closely monitored patients at Bellevue Hospital). It appears more frequently in children in the lower socioeconomic strata of society and more frequently in girls than in boys. Chronic pulmonary tuberculosis is much more frequent in children who acquire their initial infection after reaching 7 years of age and particularly if they become infected close to the onset of puberty. Cough, fever of unknown origin, chest pain, hemoptysis, and supraclavicular adenitis are the most common clinical manifestations. Essential diagnostic procedures are the tuberculin skin test and appropriate chest radiographs, often including lordotic views (with cephalic angulation). An intense search for tubercle bacilli must be made in sputum, gastric washings, and, if necessary, secretions obtained by bronchoscopy.

Myocardial and Pericardial Tuberculosis

Tubercles often are found in the heart in miliary tuberculosis. Although it is exceedingly rare, myocardial caseation has been described that is usually secondary to direct spread from mediastinal glands and accompanied by paroxysmal tachycardia or arrhythmias.⁶⁹⁰

Tuberculous pericarditis, although more common than symptomatic tuberculous myocarditis, occurred in only 0.4% of 2500 children monitored by Lincoln and Sewell³⁵³ at Bellevue Hospital, and in 4% of 200 children in Boyd's series.⁵⁹ TB accounts for approximately 70% of all pericarditis cases in sub-Saharan Africa.²⁷⁰ In most cases, tuberculous pericarditis probably arises by direct invasion or by lymphatic drainage from caseous lymph nodes in the subcarinal area or from nodes close to the ductus arteriosus, with resulting exudation of hemorrhagic fluid and the development of granulation tissue on both the parietal and visceral surfaces of the pericardium. Pericardial fluid may be serofibrinous or hemorrhagic; tubercle bacilli rarely are found on smears.²⁶³ Sometimes, extensive fibrosis leads to obliteration of the pericardial sac, with the development, usually years later, of constrictive pericarditis.

The initial symptoms generally are nonspecific: low-grade fever, poor appetite, failure to gain weight, and, rarely, chest pain. On examination, a pericardial friction rub may be heard, or if a large effusion already is present, distant heart sounds, tachycardia, and a narrow pulse pressure may suggest the diagnosis. The diagnosis then is confirmed by radiography, echocardiography, electrocardiography (widespread ST-segment elevation or PR depression; dampened voltages in the presence of a large pericardial effusion), tuberculin skin test, and aspiration of fluid for culture. Culture yield is higher for pericardial tissue than for pericardial fluid. In one study, IGRAs were more sensitive than pericardial adenosine deaminase levels and Xpert MTB/RIF for the diagnosis of tuberculous pericarditis.⁴⁷⁷ Before the advent of chemotherapy, approximately half the patients succumbed. Now, with appropriate drugs and corticosteroids to diminish the size of the effusion⁶³⁰ and also occasional partial pericardiectomy, the outlook is excellent.

Lymphohematogenous Spread

Tubercle bacilli from the lymphadenitis of the primary complex are disseminated during the incubation period in all cases of tuberculosis infection. The results of liver biopsy of young asymptomatic tuberculin converters (indicating recent infection) show that the liver always is involved.¹¹¹ Tubercle bacilli can reach deep, distant organs through the bloodstream or lymphatic channels. Autopsies on individuals who have died soon after development of initial infection show that bacilli often are deposited in the liver, spleen, skin, and apical pulmonary tissue.

The clinical picture produced by lymphohematogenous spread probably is determined by host susceptibility at the time of spread and by the quantity of tubercle bacilli released.^{571,674} Three clinical forms can be recognized:

1. The lymphohematogenous spread may be occult, in which case it usually remains so, or it may be occult initially with metastatic, extrapulmonary lesions appearing months or years later (e.g., renal tuberculosis).⁵¹⁴
2. So-called protracted hematogenous tuberculosis, rarely seen today, is characterized by high, spiking fever, marked leukocytosis,

hepatomegaly and splenomegaly, and generalized lymphadenopathy, sometimes with evidence of metastatic seeding in the choroid, kidneys, and skin. Calcifications may appear subsequently, often in large numbers, in the pulmonary apices (Simon foci) and in the spleen, thus attesting to the earlier dissemination of tubercle bacilli through blood. The tuberculin skin test result usually is strongly positive. Bone marrow biopsy may confirm the clinical impression, but treatment often must be started on a presumptive basis.⁵²² Although this type of tuberculosis in past years often ended tragically in tuberculous meningitis, today it is completely treatable if it is diagnosed in time.

3. The third form of lymphohematogenous spread, analogous to sepsis with pyogenic bacteria, is miliary tuberculosis.⁵⁷¹ It usually arises from discharge of a caseous focus, often a lymph node, into a blood vessel such as a pulmonary vein; it may be self-propagating, with repeated discharge arising at various sites. Most common during the first 2 to 6 months after infection in infancy, it can arise even in adults who have apparently well-healed, calcified lesions.^{310,553}

Miliary disease provides a striking illustration of the difference in susceptibility of tissue to tubercle bacilli; tubercles tend to be larger and more numerous in the lung, spleen, liver, and bone marrow than in the heart, pancreas, and brain. The number of fixed intravascular phagocytes, as well as the relative tortuosity of the smaller blood vessels themselves, must play an important role in determining tissue susceptibility. In acute caseating miliary tuberculosis, the lesions are likely to be numerous and sometimes almost coalescent.

The clinical picture of miliary tuberculosis varies greatly, probably depending on the number of bacilli in the bloodstream. Sometimes, the patient is afebrile and appears to be well, and the condition is diagnosed by chance during contact investigation of another individual with infectious tuberculosis. The onset can be insidious, often occurring after the patient has had another precipitating infection. In rare cases, the onset is abrupt. Drowsiness, loss of weight and appetite, persistent fever, weakness, rapid breathing with a rustling sound on auscultation of the lungs, occasionally cyanosis, and almost always a palpable spleen are the clinical manifestations that lead the clinician to obtain a chest radiograph.

Usually within no more than 3 weeks after the onset of symptoms, tubercles can be seen evenly distributed throughout both lung fields⁴⁶⁵; in the early stages, they often are detected best on a lateral view of the retrocardiac space (Fig. 96.11). The incidence of choroidal tubercles varies greatly; it has been reported variously as 13% and 87%. Recurrent pneumothorax (including tension pneumothoraces), subcutaneous emphysema, pneumomediastinum, and pleural effusion are well-recognized complications of miliary tuberculosis. Cutaneous lesions,

including painful nodules, papulonecrotic tuberculids, and purpuric lesions, may appear in crops.³⁰⁴

The diagnosis usually is established by means of the clinical picture and a chest radiograph. Sometimes it is confirmed by a liver or skin biopsy; by culture of *M. tuberculosis* from the gastric aspirate, urine, or bone marrow^{111,236}; or by fiberoptic bronchoscopy and transbronchial biopsy.⁶⁹ Treatment usually is successful.

Extrathoracic Spread

Central Nervous System Tuberculosis

Tubercle bacilli are distributed by the bloodstream into all parts of the central nervous system (CNS) during lymphohematogenous spread.^{352,607}

Surprisingly, they do not multiply as well in nervous tissue as in other areas such as the lung. Thus, CNS tuberculosis, although an early manifestation of infection, usually does not appear simultaneously with miliary spread but days later. The tubercle bacilli can affect the CNS in various ways^{667,685} and produce tuberculous meningitis,^{267,633} serous meningitis,^{347,667} tuberculoma,^{660,667} or tuberculous brain abscess, or it can affect mainly the spinal cord and cause spinal tuberculous leptomeningitis.⁴⁵⁶

Tuberculous meningitis arises from caseous foci⁵¹⁵ that discharge tubercle bacilli directly into the subarachnoid space. The thick, gelatinous exudate lies in the meshes of the pia-arachnoid in the brain, where it infiltrates the walls of meningeal arteries and veins and produces inflammation, caseation, and obstruction; the exudate can extend along small vessels into the cortex, where it causes occlusion and produces infarcts. This same exudate interferes with normal flow of cerebrospinal fluid (CSF) in and out of the ventricular system and with CSF absorption. The predilection of the exudate for the base of the brain accounts for the frequent involvement of the third, sixth, and seventh nerves and the optic chiasm. The combination of vascular lesions producing infarcts,³⁴² interference with CSF flow resulting in hydrocephalus, and direct cranial nerve involvement, especially of the eye, causes the devastating damage that all too often results from tuberculous meningitis.²⁰

Tuberculous meningitis has been estimated to develop in one of every 300 untreated infections.²⁷⁹ Virtually never seen in infants younger than 4 months, it occurs most frequently in children younger than 6 years, usually appears within 2 to 6 months after initial infection, and accompanies miliary tuberculosis in approximately 50% of cases. Tuberculosis should be suspected as the cause of meningitis that is accompanied by cranial nerve involvement, hydrocephalus, or evidence of inflammation at the base of the brain.⁶⁷²

The onset of tuberculous meningitis usually is gradual and occurs during a period of approximately 3 weeks. On occasion, the onset is abrupt and marked by a convulsion. A convenient approach is for the

FIG. 96.11. Miliary tuberculosis in an infant. The numerous tubercles can be seen on both the (A) posteroanterior and (B) lateral views.

clinician to divide the course into three stages. The first stage is characterized by personality change, irritability, anorexia, listlessness, and some fever. After 1 or 2 weeks, the disease passes into the second stage, when signs of increased intracranial pressure and cerebral damage appear: drowsiness, stiff neck, cranial nerve palsies, inequality of the pupils, vomiting, absence of the abdominal reflexes, and convulsions that may be tonic or clonic and focal or generalized. The third stage is characterized by coma, irregular pulse and respirations, and rising fever. Papilledema occasionally is noted.

Aids in establishing the diagnosis are a history of contact with an adult who has tuberculosis (however, the family history of tuberculosis often is “negative” because the incubation period of meningitis is short and the contagious adult has not been discovered yet)¹⁵⁵; a tuberculin skin test (positive result in only 50% of cases); positive tuberculin skin test results in siblings; a chest radiograph, which often reveals pulmonary disease; and changes in, and the characteristic findings from, CSF. However, the ventricular CSF may be relatively normal because it is obtained proximal to the site of inflammation. The lumbar CSF usually is clear and under substantially increased pressure. It will contain 50 to 500 white blood cells/mm³, with polymorphonuclear leukocytes predominant early and lymphocytes predominant later. The CSF glucose level may be at the lower limits of normal if the patient is examined early in the second stage, and it falls by 5 mg or so each day; by the third stage, hypoglycorrhachia is profound. The protein content may be normal at the time of the first lumbar puncture, but it rises steadily to very high concentrations. Tubercle bacilli are scarce. Only 30% to 50% of cases of tuberculous meningitis in children can be confirmed by culture of CSF; CSF acid-fast smear positivity is seen in fewer than 10% of cases. Gastric washings should be cultured, not only to confirm the diagnosis in retrospect but also to permit drug susceptibility testing of the organisms.⁷²³

CT or magnetic resonance imaging (MRI)^{18,20,225,461,707} is recommended for the evaluation of all patients with tuberculous meningitis. Both permit recognition and follow-up of tuberculomas,^{666,703} infarction or vasculitis, and hydrocephalus that might require shunting.^{20,131,285,624} Involvement of the basal ganglia often is a diagnostic clue for the presence of tuberculosis.¹⁸ High levels of antidiuretic hormone (the syndrome of “inappropriate” antidiuretic hormone secretion [SIADH]) may cause hypotonic expansion of the extracellular fluid. Hyponatremia is a nonspecific finding seen with various causes of vasculitis. Salt wasting in the urine occurs in rare cases. Because intense vomiting and dehydration usually accompany tuberculous meningitis, the electrolyte disturbances usually include severe hypochloremia.

A good prognosis depends on immediate initiation of treatment without awaiting epidemiologic and bacteriologic confirmation of the diagnosis.^{264,528} Before chemotherapy was used, every case of true tuberculous meningitis was fatal within 3 to 4 weeks, whereas today appropriate treatment during the first stage allows survival in nearly every case, although the patient’s intelligence may never return to its previous level. Unfortunately, the nonspecific signs and symptoms of stage 1 TB meningitis mean that few children are diagnosed at this early stage. When treatment is initiated during the second stage, treatment results in survival in 75% or more of patients. If patients are obtunded or comatose when treatment is begun, they rarely recover unscathed. Very young age and the occurrence of convulsions generally are poor prognostic factors.^{528,550} Hydrocephalus, usually of the communicating type, occurs frequently (38% in one series) and is largely responsible for poor outcomes. Relieving the hydrocephalus surgically appears to improve the sensorium, vision, and neurologic deficits. Studies support the early use of ventriculoperitoneal shunting in patients severely ill at the time of admission.^{329,475} Some neurosurgeons may prefer to place an external ventricular drain initially if there is concern that the high CSF protein levels could result in shunt malfunction. Infarcts caused by vasculitis also can leave catastrophic residua. The presence of drug-resistant tuberculous meningitis greatly worsens the prognosis,⁴⁷⁴ as does coinfection with HIV.⁶⁸⁷ The role of corticosteroids in the treatment of intracranial tuberculosis is discussed later in this chapter.

The long-term sequelae of tuberculous meningitis are numerous and include blindness, deafness, intracranial calcification, diabetes insipidus, syndrome of inappropriate antidiuretic hormone secretion,

obesity, paraplegia, and mental retardation.⁵⁵⁰ A recent meta-analysis found that the mortality rate for TB meningitis was 19% and that the probability of neurologically intact survival was only 37%.¹⁰⁷

Serous tuberculous meningitis is an uncommon occurrence (13% of 500 cases in the experience of Udani and associates⁶⁶⁷). Apparently, it develops when a tuberculous focus close to the subarachnoid space causes a lymphocytic reaction in the subarachnoid space without the actual presence of tubercle bacilli.⁷²⁸ Isolated tuberculoma is manifested clinically as a brain tumor.^{26,141,156} As many as 30% of mass-occupying CNS lesions are tuberculomas, depending on the incidence of tuberculosis in the particular population under study (e.g., in India). Tuberculomas occur most often in children younger than 10 years old and often are located at the base of the brain around the cerebellum.⁶⁸⁶ In contrast, tuberculomas in adults more often are supratentorial. Headache, convulsions, fever, and other symptoms and signs usually associated with brain abscess or tumor also characterize tuberculoma. Only careful evaluation, including inquiry about exposure to tuberculosis, a TST, chest radiography, and a CT, will permit these cases to be recognized in time to begin appropriate chemotherapy before neurosurgical intervention is needed. The widespread use of neuroimaging has revealed that small, multiple tuberculomas are a frequent feature of tuberculous meningitis in infants and young children.^{18,20} A phenomenon recognized fairly recently is a symptomatic intracranial tuberculoma appearing and enlarging during treatment of meningeal, miliary, and even pulmonary tuberculosis.^{6,339,507,572,649} This phenomenon appears to be mediated immunologically; it usually responds to corticosteroids and does not necessitate a change in antituberculosis chemotherapy. In addition, some small children with severe pulmonary or disseminated tuberculosis have one or several tuberculomas but normal findings on CSF evaluation.^{155,280} CT or MRI of the head should be performed whenever neurologic signs or symptoms accompany tuberculosis.

Tuberculous brain abscess is a rarely reported form of CNS tuberculosis that tends to occur at an older age than tuberculoma does.^{323,702} On pathologic examination, the lesion lacks the giant cell and granulomatous reaction associated with tuberculoma. Focal neurologic signs occur commonly. CT and MRI, if used routinely in cases of tuberculous meningitis, may permit this type of abscess, which requires surgical intervention as well as chemotherapy, to be recognized more frequently. Intramedullary tuberculoma of the spinal cord is exceedingly rare. It can be manifested as recurrent abdominal pain.

Spinal tuberculous leptomeningitis occurs more often in older children and adults than in infants; in the series of 500 cases studied by Udani and coworkers,⁶⁶⁷ only 2% fell into this last age group. Protein levels in the CSF are elevated substantially, and sometimes partial or total block may be noted on myelography. Exudate may completely surround the spinal cord.

Cutaneous Tuberculosis

The manifestations of cutaneous tuberculosis can be classified in children according to a modification of the earlier classifications designed for adults:³²⁴ (1) lesions produced by inoculation from an exogenous source⁴⁹³ or after inoculation with BCG vaccine; (2) lesions resulting from hematogenous dissemination³⁰⁴; (3) lesions arising from an endogenous source; and (4) erythema nodosum.

Skin lesions associated with the primary complex may be caused by direct inoculation of tubercle bacilli into a traumatized area, such as a lesion on the sole of a child’s bare foot, a mosquito bite on the face, an abraded elbow, or the foreskin at the time of ritual circumcision.^{478,560} The initial skin focus usually is a small, painless nodule, sometimes with tiny satellite lesions that soon turn into indolent ulcers without surrounding inflammation. The most striking feature is painless regional lymphadenitis, which often is what convinces the patient to see a physician. Fever and systemic reactions generally are minimal; low-grade pyogenic infection and cat-scratch fever (*Bartonella* infection) always must be considered in the differential diagnosis. A strongly positive TST result usually is obtained. Needle aspiration and culture may differentiate disease caused by *M. tuberculosis* from that caused by nontuberculous mycobacteria.

Scrofuloderma indicates tuberculosis of the skin overlying a caseous lymph node (most often in the cervical area) that has ruptured to the

outside and left either a shallow ulcer or a deep sinus, sometimes surrounded by a cluster of nodules. Today, it is a rare occurrence because the diagnosis generally is made before the node ruptures. Administration of chemotherapy often forestalls the need for surgical excision. Needle aspiration of fluctuant nodes can help with decompression and may decrease the risk of sinus tract formation.

Manifestations that result from hematogenous dissemination are papulonecrotic tuberculids and tuberculosis verrucosa cutis. Papulonecrotic tuberculids⁵⁸⁰ are miliary tubercles in the skin that usually appear as tiny papules with “apple jelly” centers, most often on the trunk, thighs, and face. They frequently are similar to papular urticaria or early varicella lesions, or they may be confused with the skin lesions of Letterer-Siwe disease. Skin biopsy provides a reliable diagnosis. Lupus vulgaris is a rare form of chronic, indolent tuberculosis, usually on the face, that often seems to evolve from tuberculids, very rarely at the site of BCG inoculation.

Tuberculosis verrucosa cutis is a condition characterized by large (several centimeters in diameter) papulonecrotic tuberculids. The lesions usually appear on the arms, legs, or buttocks, suggesting that trauma may play some part in their causation. Fungal infection is the main consideration in the differential diagnosis.

Erythema nodosum formerly was a common manifestation of hypersensitivity to tuberculin. It occurs mostly in teenage girls. Usually beginning with fever and systemic toxicity manifesting soon after initial infection develops, erythema nodosum is characterized by large, deep, painful, indurated nodules on the shins and sometimes on the thighs, elbows, and forearms. The nodules gradually change from light pink to a bruise-like color. Erythema nodosum is not specific for tuberculosis but also occurs with streptococcal and meningococcal infections, histoplasmosis, coccidioidomycosis, sarcoidosis, drug sensitivity reactions, and perhaps cat-scratch disease. Tuberculin hypersensitivity is pronounced in children with tuberculosis underlying erythema nodosum, and tuberculin skin testing should be performed with caution. These patients may or may not have associated tuberculous lesions, but some clinicians hold that these patients have a greater chance of suffering complications. Skin biopsy reveals only nonspecific changes regardless of cause and, therefore, is useless in establishing the diagnosis. Both fever and nodules clear within 2 or 3 weeks.

Skeletal Tuberculosis

Bone and joint tuberculosis can be expected in 1% to 5% of children whose initial infection with tubercle bacilli is untreated. Usually, the tubercle bacilli are disseminated to skeletal structures during lymphohematogenous spread of the initial infection.³³ The disease becomes symptomatic during the first 1 to 3 years after infection. Each of the most frequently involved bones and joints has a characteristic “incubation period” (e.g., 1 month for dactylitis but about 30 months for tuberculosis of the hip). In very young children, blood flow through growing bone is intense; consequently, they suffer from skeletal tuberculosis more often than older children do. The lesion usually starts as an area of endarteritis in the metaphysis of the long bone, where the blood supply is particularly abundant; lesions can be single or multiple.^{504,570} Bone infection can be initiated by two other mechanisms, particularly in the vertebrae: (1) direct extension through the lymphatics from a caseous paravertebral lymph node⁷⁰ and (2) direct local hematogenous or lymphatic extension from a neighboring bone. As bone is destroyed progressively by pressure necrosis and formation of a cold abscess, a nearby joint may become involved.^{505,670,687}

The bones most often affected are the vertebrae.⁴⁶⁴ In one study of 1074 patients with the disease, 41% had vertebral involvement, 8% each had hip or knee involvement, and 5% had elbow involvement.⁶⁶⁴ Non-weight-bearing bones, such as the skull, clavicle, and mandible, rarely are involved.^{235,239} Often a history of trauma is present and may play some part in activation of an underlying lesion or may serve simply to draw attention to the process.

Tuberculous spondylitis, or tuberculosis of the vertebrae, frequently affects the thoracic vertebrae, particularly the 12th one.²⁴⁶ In one series of 64 cases of spinal tuberculosis in children, thoracic lesions were most common (38%), followed by lumbar involvement (29%); in 20%, both the thoracic and lumbar spine were involved. Cervical involvement is

rare.²⁵⁸ Usually, two vertebrae are involved, but sometimes 3, 4, or even as many as 11 (usually contiguous, but at times with “skips”) are affected. The body of the vertebra is affected far more often than the spinous processes or the arch.

The progression of tuberculous spondylitis, as seen on radiographs, is from slight narrowing of the disk space with only minimal disk involvement and slight collapse and “wedging” of the vertebral body to marked narrowing of the disk space with collapse, wedging of the bodies, and resulting angulation of the spine (gibbus), and to extensive destruction of the bodies with severe kyphosis (Pott disease).

Paravertebral abscess (Pott abscess), retropharyngeal abscess, psoas abscess, and neurologic lesions are serious complications seen in 10% to 30% of cases of spondylitis. Neurologic complications most often arise from cervical and lumbar vertebral lesions and consist of various degrees of neuroplegia, paraplegia, or even quadriplegia. The complications are caused by inflammation of the spinal cord secondary to a neighboring cold abscess, by caseum or granuloma in the extradural space, or by spinal vessel thrombosis.

The signs and symptoms of spondylitis include pain that is worse at night, low-grade fever, and a peculiar position (e.g., torticollis with cervical lesions) or gait. Findings on physical examination may include marked “guarding” because of dorsal muscle spasm, pain when the back is “pounded,” a gibbus deformity (e.g., acute angle thoracolumbar kyphosis), or reflex changes (including clonus).³⁹⁹ On occasion, the presence of referred chest pain leads to discovery of a paravertebral abscess on the chest radiograph. With chemotherapy and, when necessary, surgery, the outlook for both eventual clinical healing and neural recovery is in the range of 80% to 90%, although patients may not gain their full expected height.

Tuberculosis of the knee can be divided into several clinical types²⁴⁵: isolated effusion (with little restriction of motion); synovial thickening and fibrosis of the synovial membrane without bone erosion (with considerable restriction of motion); or synovial disease and a bone focus but an intact joint space.⁶²⁷ Some degree of pain, stiffness, and limping, usually intermittent in milder cases, first calls attention to the problem.

Tuberculosis of the hip, in some series of patients more common than tuberculosis of the knee, should be considered in the differential diagnosis of the child with an antalgic gait or refusal to weight bear. Isolated involvement of the acetabulum or femoral head without intraarticular disease has a good prognosis.

Tuberculous dactylitis (spina ventosa)²³¹ is the most common form of skeletal tuberculosis in infants. Enderteritis is followed by swelling (often painless), and cystic bone lesions are seen on radiographs. A cold abscess may form and drain spontaneously. The prognosis for recovery without deformity is surprisingly good and was so even before chemotherapy was available.

Tuberculous arthritis is rare in children. Usually monoarticular, it involves primarily the weight-bearing joints; upper extremity involvement is rare. Bacterial cultures and histologic examination of the synovium establish the diagnosis.⁶⁸⁷ Poncet disease is a form of rheumatic joint disease associated with tuberculosis characterized by nondestructive, transient, migratory polyarthritis. Poncet disease is exceedingly rare in children.¹³⁶ The diagnosis of skeletal tuberculosis should be considered immediately in any child with known TB infection in whom a bone or joint lesion develops and in any child with a persistent, otherwise unexplained bone or joint lesions.⁶⁸² The differential diagnosis must include low-grade infections caused by *Staphylococcus*, *Haemophilus influenzae*, *Salmonella*, and *Brucella*; fungal infections; rheumatoid arthritis; malignancy; eosinophilic granuloma, particularly with skull or pelvic lesions; and osteochondrosis resulting from aseptic necrosis of bone, particularly Legg-Calvé-Perthes disease and tuberculosis of the hip.

Children with bone and joint tuberculosis usually react strongly to tuberculin. Chest radiographs are abnormal in up to 50% of children with TB skeletal disease. Although the number of tubercle bacilli in an active bone lesion is much lower than in a lung lesion, the organisms almost invariably can be recovered on culture, and a great effort to do so should be made by means of aspiration or open biopsy.²²²

Treatment of skeletal tuberculosis includes both chemotherapeutic and orthopedic interventions, with the chemotherapeutic interventions

by far the more important.⁵⁰² Orthopedic procedures can be used for several purposes: establishment of the diagnosis, evacuation of caseum and necrotic bone, immobilization of a joint, and reconstruction or strengthening of damaged bone. Since the advent of chemotherapy, any indicated surgical procedure can be performed without fear of subsequent development of sinus formation. However, the trend has been toward reliance on drug therapy with increasingly conservative surgical management. Controlled trials of treatment undertaken in different parts of the world (Southeast Asia) by the Medical Research Council Working Party on Tuberculosis of the Spine and others have demonstrated the remarkable effectiveness of ambulatory treatment with different regimens of chemotherapy in children and adults,^{271,403–405} including short-course chemotherapy.²²⁹

Tuberculosis of the Superficial Lymph Nodes (Scrofula)

Striking enlargement of the superficial regional lymph nodes is an integral component of the primary tuberculous complex. The tonsillar and submandibular nodes are involved most often and probably represent extension from the paratracheal lymph nodes (and not from a primary lesion in the tonsil, as once was thought); occasionally, these nodes are involved when the primary lesion occurs in the mucous membranes of the mouth, a rare event. Enlarged supraclavicular nodes may accompany a primary pulmonary lesion in the upper lung fields.⁵⁵⁵ Enlarged axillary and epitrochlear nodes can result from a primary skin lesion of the elbow or hand, often a small, insignificant-looking area that has, however, been present for some time. Preauricular adenitis suggests a focus on the scalp or forehead or in the lacrimal sac, sometimes attributed to an insect bite. With inguinal adenitis, careful examination of the sole of the foot may reveal a small ulcer, often at the base of the toes.

When the superficial lymph nodes are involved early in the course of infection—the normal event—the enlargement usually is painless and the node or nodes are rubbery and discrete.³⁹⁰ Low-grade fever generally is present, sometimes unnoticed by the parents. On occasion, acute respiratory tract infections seem to precipitate or to aggravate superficial tuberculous lymphadenitis and the patient has high fever, some local pain, and perilymphadenitis. Rarely, the patient is seen first with a fluctuant mass and the overlying skin is shiny and erythematous.^{138,600}

The diagnosis usually is not obvious, so it is wise in all cases of chronic superficial cervical and supraclavicular lymphadenitis to perform a throat culture, radiography of the chest, and a TST. If the node is fluctuant, it should be aspirated and cultured for mycobacteria, as well as for pyogenic bacteria.³³² In preauricular, axillary, and inguinal adenitis, a possible primary skin lesion should be sought diligently. If a lesion is found, a biopsy should be performed, in addition to a tuberculin skin test, chest radiography, and a careful history. In one study conducted in a tuberculous hyperendemic region in children with chronic (greater than 4 week duration) lymphadenopathy whose nodes were at least 2 × 2 cm and were unresponsive to antibiotic therapy, tuberculosis lymphadenitis was diagnosed in over 90% and sensitivity was excellent.³⁹⁰ In areas with lower incidences of tuberculosis, this scoring system cannot be used.

In addition to pyogenic infection, the following need to be considered as possible causes: cat-scratch disease, tularemia, malignant tumors, sarcoid, and nontuberculous mycobacterial (NTM) infections.^{32,327} If the adenitis is caused by infection with *M. tuberculosis*, the TST induration usually is greater than 15 mm, whereas most NTM produce a less intense reaction. IGRAs can also help distinguish *M. tuberculosis* from most NTM species (a notable exception is *M. kansasii*). The key to distinguishing tuberculosis from infection by another mycobacterium generally is epidemiologic—has the child been exposed to tuberculosis?

Because infection with pyogenic bacteria often enhances mycobacterial adenitis, frequently a wise approach is to institute therapy with a conventional antibacterial agent while awaiting the results of the TST, chest radiography, and cultures. If the adenitis persists and evidence of mycobacterial infection is elicited, antituberculosis drug therapy should be initiated and surgical excision seriously considered.^{327,554} Surgical excision currently is the treatment of choice for adenitis caused by mycobacteria other than *M. tuberculosis*. In the case of lymphadenitis caused by *M. tuberculosis*, the response to antituberculosis drugs is

likely to be good. On the other hand, the adenitis is more likely to extend down into the mediastinum and to be difficult to remove. Under these circumstances, surgical excision probably is unwise, whereas a few weeks of corticosteroid and antituberculosis therapy may be effective.^{282,327}

Superficial tuberculous lymphadenitis sometimes occurs early in the course of lymphohematogenous spread, in which case it often is manifested as generalized lymphadenopathy with associated fever, malaise, and weight loss. The TST result almost always is positive in immunocompetent patients, and the TST should be included in the investigation of every patient with generalized lymphadenopathy.

Finally, tuberculous adenitis, either localized or generalized, can occur in adolescents or young adults who were infected months or even years earlier, whose infection has been quiescent, and in whom the appearance of lymphadenitis heralds reactivation of the tuberculosis infection.³²⁶

Ocular Tuberculosis

Ocular tuberculosis is an uncommon finding in children. When it does occur, the conjunctiva and the cornea are the areas most often involved.¹⁵³

The conjunctiva can serve as the initial portal of entry for tubercle bacilli, especially after trauma. Unilateral lacrimation and reddening may lead to the discovery of yellowish gray nodules, usually on the palpebral conjunctiva. Preauricular adenitis appears early; the submandibular and cervical nodes also may enlarge. A TST and biopsy of the lymph node with culture can be performed to confirm the diagnosis.

Phlyctenular conjunctivitis probably is one of the hypersensitivity phenomena of childhood tuberculosis. Tubercle bacilli have, on rare occasion, been isolated from the small, grayish, jelly-like nodules usually clustered on the limbus and surrounded by dilated conjunctival vessels. Pain and photophobia are intense, and the lesions may recur in crops for weeks and affect one or both eyes. In the differential diagnosis, foreign body, herpes simplex virus conjunctivitis, vernal conjunctivitis, and trachoma should be considered. Tuberculin sensitivity is likely to be pronounced, and 1 tuberculin unit of purified protein derivative (PPD) should be used in the initial tuberculin skin test. Fortunately, hydrocortisone drops are effective in controlling both a strong local reaction to the diagnostic tuberculin test and the discomfort from the underlying disease. The prognosis for complete recovery is excellent, provided the phlyctenules do not ulcerate and leave corneal scars. Systemic chemotherapy should be started immediately after the diagnostic procedures are completed. The data for systemic corticosteroids are heterogeneous, but many experts would consider a 4- to 6-week course of systemic corticosteroids for ocular manifestations of tuberculosis.

Although tuberculosis of the ciliary body and iris has been reported rarely in children, tubercles of the choroid often have been found in patients with miliary tuberculosis (up to 70% of patients in some series) and occasionally in children with a seemingly uncomplicated infection.^{428,462} Frequently multiple, the tubercles heal slowly with deposition of retinal pigment; residual scarring apparently can be prevented with corticosteroid therapy. Tuberculous uveitis and tuberculosis manifested as an orbital mass are rare clinical entities.⁵⁷³

Tuberculosis of the Middle Ear

Tuberculosis of the middle ear is a relatively rare manifestation of the disease.^{187,365,367,434,534} It occurs as a primary focus in the area of the Eustachian tube (because of reflux up the tube) in neonates who have aspirated infected amniotic fluid, or in older infants who have ingested tuberculous material. It can occur as a metastatic lesion in older children who have a primary focus elsewhere. If it is a primary focus, regional lymphadenitis involves the preauricular lymph node or the anterior cervical chain and facial paralysis occurs frequently. The primary focus always is unilateral. Chronic painless otorrhea is a common occurrence and may become foul smelling because of bacterial contamination with enteric organisms. Direct intracranial extension is rare, but contiguous involvement of the mastoid can be seen. Older patients may complain of tinnitus and “funny noises.” The eardrum often is damaged extensively. A large central perforation or several perforations are characteristic findings. MRI is superior to CT in visualizing abscesses and bony destruction, and for monitoring response to therapy radiographically.⁴³⁰

A TST, biopsy, and careful cultures for tubercle bacilli are essential. Once greatly feared for the almost inevitable loss of hearing and the frequent occurrence of tuberculous meningitis, tuberculous otitis media now heals well with appropriate chemotherapy.⁴³⁴

Gastrointestinal and Abdominal Tuberculosis

Tuberculosis of the mouth occurred more commonly in the days of bovine tuberculosis than it does today; at that time, scrofula often represented a primary complex in the mouth or tonsils, with associated submandibular or cervical lymphadenitis.⁴¹⁴ A primary focus in the mouth generally consists of a painless ulcer or mass of granulation tissue around a tooth socket or in the gingivolabial sulcus, with enlarged submental or submandibular nodes. Primary tuberculosis of the tonsils begins as a painless swelling of one tonsil, sometimes with an ulcer or yellowish node and, of course, enlargement of the regional lymph nodes. If tubercles found on histologic examination of a tonsil removed at tonsillectomy are unaccompanied by lymphadenitis, the lesion is considered a metastatic rather than a primary lesion. Tuberculosis of the esophagus occurs rarely, if ever, in children; sometimes, dysphagia is produced by a mass of mediastinal nodes, which may rupture into the lumen and later heal, possibly leaving an esophageal diverticulum.

Abdominal tuberculosis may occur after the ingestion of tubercle bacilli or as a part of generalized lymphohematogenous spread, but tuberculous enteritis always has been uncommon.^{19,46,525,637,640} When tubercle bacilli penetrate the gut wall, they usually do so through the Peyer patches or the appendix, where they give rise to local ulcers followed by mesenteric lymphadenitis and sometimes peritonitis.¹⁹ On occasion, especially in older children, tuberculous enteritis accompanies extensive pulmonary cavitation. Symptoms and signs include vague abdominal pain, intussusception, blood in the stool, and sinus formation after a seemingly routine appendectomy.

The spleen is seeded during the initial lymphohematogenous spread. Only rarely are the tubercles numerous and large enough to undergo caseation and to calcify.³¹⁶ The reticuloendothelial system of the liver is involved also. Symptoms rarely are manifested except in miliary tuberculosis, in which the liver may be enlarged markedly, or in congenital tuberculosis, in which both the liver and spleen usually are enlarged.³⁷¹

Mesenteric lymphadenitis can arise as part of an intraabdominal primary complex or by extension from tuberculous thoracic or pelvic lymph nodes; often asymptomatic, it may be discovered later when calcified. It can cause ascites and dilation of the superficial abdominal veins, but the symptom most frequently attributed to mesenteric lymphadenitis is colicky abdominal pain after exercise, probably because adhesions are stretched.

Tuberculous peritonitis can be a result of direct extension from a primary intestinal focus, adjacent mesenteric lymph nodes, or tuberculous salpingitis.^{104,152,208} It may be "plastic" or accompanied by a serous effusion. On palpation, a mass of lymph nodes often can be felt and the abdomen may have a characteristic "doughy" feeling. Paracentesis should be performed with care because the intestine may be immobilized by adhesions. Even with a large effusion, absorption usually occurs within a month. Malignant disease must, of course, be considered strongly in the differential diagnosis, and it may be necessary to obtain a biopsy specimen even if the tuberculin skin test result is positive. Laparoscopy frequently is useful, as is fine-needle aspiration³⁵⁹ and ultrasonography.²⁹³ CT is more sensitive than ultrasound. CT findings may include lymphadenopathy (often with central necrosis and rim enhancement), solid masses, and multiseptal symmetrical intestinal mural thickening.⁷²⁷ CT is less helpful for ascites, as it does not detect septations well.⁶⁷⁷ The ascitic fluid–blood glucose ratio of the aspirated peritoneal fluid can be helpful in differentiating tuberculous peritonitis from ascites of other causes.⁷⁰³

Renal Tuberculosis

Renal tuberculosis is a late and uncommon complication of pulmonary disease; it rarely occurs less than 4 or 5 years after primary infection and is therefore likely to be diagnosed during adolescence.^{182,587} However, tubercle bacilli can be recovered from the urine in many cases of miliary tuberculosis and some cases of pulmonary tuberculosis in young children.

Hematogenous dissemination can give rise to tubercles in the glomeruli, with resultant caseating and sloughing but tiny lesions, which then discharge tubercle bacilli into the tubules. An encapsulated caseous mass occasionally develops in the zone between the renal pyramid and cortex; it may calcify in situ or discharge into the pelvis of the kidney and form a cavity analogous to a pulmonary cavity. Infection can be unilateral or bilateral and can spread downward to involve the bladder. Frequently, dysuria, hematuria, and "sterile" pyuria are the initial findings in the urine; they may occur grossly but often not until late in the course of a disease that causes strikingly few symptoms. CT findings can include renal parenchymal cavities, hydronephrosis, ureteral strictures, and thickening of the renal pelvis or ureter.⁵³² Appropriate examination and culture of single early-morning urine specimens rarely fail to reveal tubercle bacilli. Intensive chemotherapy renders surgical intervention a rare necessity.⁵⁸⁷ Urine from patients with renal tuberculosis is highly infectious, and such children should be isolated until their urine is sterile.

Dialysis- and Renal Transplant–Associated Tuberculosis

Infections are a common cause of morbidity and mortality in patients with end-stage renal disease. The frequency of extrapulmonary disease is higher in dialysis recipients, and one recent study of adults receiving dialysis in the United Kingdom found that one-fourth of patients had drug-resistant isolates.⁴⁶⁹ Depressed cellular immunity, as manifested by cutaneous anergy, delayed homograft rejection, and depressed lymphocyte count, has been demonstrated in uremic patients, whereas cell-mediated immunity appears to recover in stable patients treated by long-term hemodialysis. Thus, it is not surprising that tuberculosis occurs more frequently in patients maintained on dialysis than in the general population and that when it does become active, it does so before or early in the course of dialysis. Extrapulmonary involvement (mediastinal, meningeal, pleural, osseous, and renal) and miliary tuberculosis appear relatively frequently in this group. In these patients, fever of unknown origin should lead to suspicion of active tuberculosis.¹⁵ Tuberculosis also can originate in the transplanted organ.^{437,681}

Genital Tuberculosis

Tuberculosis of the genital tract is an uncommon finding in both sexes before puberty.⁵⁸⁷ It usually arises as a metastatic lesion during lymphohematogenous spread and occasionally by direct extension from an adjacent lesion of bone, gut, or the urinary tract. Genital tuberculosis is a particular hazard for adolescent girls with tuberculosis infection. Frequently, other forms of tuberculosis associated with initial infection, such as a pleural effusion, also are present. Acute or chronic salpingitis is the most common manifestation (seen in over 90% of cases). This results in nodular thickening and a "corkscrew" appearance of the fallopian tubes, and, ultimately, tubular obstruction. Endometritis is seen in 50% of cases and is characterized by intrauterine adhesions. Ovarian involvement (in 20–30%) may include perioophoritis (from direct spread from the fallopian tubes) and tuboovarian masses. Cervical involvement is seen in 5% to 20% of cases; cervical stenosis is the most common finding, and this results in infertility in one-half of cases.^{547,567} With tubal involvement, peritoneal tuberculosis occurs frequently.

Lower abdominal pain and amenorrhea usually prompt the patient to seek medical care. A lower abdominal mass, free peritoneal fluid, and constitutional symptoms may or may not be present. Chemotherapy is effective, but infertility remains a potential sequela of the disease.

Tuberculosis of the external genitalia has been seen as a manifestation of child abuse.

Genital tuberculosis can occur in males as primary tuberculosis of the penis after ritual circumcision; many such instances were reported in the past.^{248,478} Massive inguinal lymphadenopathy in a circumcised infant should arouse suspicion of a possible tuberculous etiology. Epididymitis or epididymo-orchitis can occur in early childhood.²¹⁷ These disorders are characterized by nodular, painless swelling of the scrotum, and a dragging pain in the groin and have a gradual onset rather than the acute onset that results after trauma, torsion of the testis, mumps orchitis, or epididymitis associated with bacterial infection.

Inoculation Tuberculosis

More than 200 cases of syringe-transmitted tuberculosis have been described in the world literature.²⁴⁴ It has become more common since the widespread use of injectable penicillin and routine childhood immunization and usually has been a result of contamination of the syringe or the solution by an individual with infectious sputum. If the recipient has not been infected previously, the lesion in the muscle or subcutaneous tissue will be the primary focus and the regional lymph nodes will enlarge, caseate, and, under favorable circumstances, calcify. However, at least 10 infants thus infected have died as a result of generalized tuberculosis, and in others bone tuberculosis has developed. If the recipient already is tuberculin positive, a tuberculous abscess will form without regional lymphadenitis. In this case, an injection abscess must be differentiated from a deep tuberculous abscess arising in the stage of hematogenous dissemination.

Perinatal Tuberculosis (Congenital and Postnatal)

Transmission of *M. tuberculosis* from mother to infant through the placenta or amniotic fluid has been reported in approximately 300 patients.⁷⁶ Infection of the placenta has been demonstrated, and tubercle bacilli have been grown from the tissues of stillborn infants and from living infants within a few days of birth. Perinatal tuberculosis can be acquired by the infant through one of several routes:

1. Transplacental spread through the umbilical vein from a mother with primary hematogenous tuberculosis occurring during pregnancy (i.e., true congenital tuberculosis). The liver is enlarged, enlarged lymph nodes may be present at the porta hepatis, and evidence of widespread miliary disease may be seen in the infant (i.e., the infant may have a primary liver complex or primary lung complexes).
2. In utero aspiration of amniotic fluid infected from endometritis in the mother or from the placenta. This route of infection also constitutes true congenital tuberculosis. In both these situations, clinical onset of signs and symptoms is likely to be rapid (by 2 to 3 weeks of age) and to include failure to thrive, fever, respiratory distress, and hepatosplenomegaly.
3. Ingestion of infected amniotic fluid or secretions during delivery. This mechanism would seem to be less well documented than the first two routes, but it certainly is a possibility.
4. Inhalation of tubercle bacilli at or soon after birth from the mother, other relatives, or attendants with infectious pulmonary tuberculosis. This route is the most common mode of transmission to neonates.
5. Ingestion of infected breast milk or cow's milk.

One cannot always be sure of the type of infection in a particular neonate; only clear-cut evidence of a primary complex in the liver establishes a definite diagnosis of congenital tuberculosis. However, the presence of early forms of tuberculosis (e.g., pleural, miliary, or meningeal) in the mother during pregnancy or the puerperium also is strong evidence of true congenital tuberculosis in the infant.

The last two listed routes are really means of "postnatally" acquired tuberculosis and need, for epidemiologic purposes, to be distinguished from the first three routes. Neonates with these types of tuberculosis usually lack striking clinical features until they are 1 or 2 months of age.

The diagnosis of perinatal tuberculosis is likely to be difficult to establish and often delayed.³³⁶ Disease in the mother often is overlooked; the mother may have pleural effusion, fever of unknown origin, cough, endometritis, and other symptoms without the tuberculous etiology being recognized. The early symptoms and signs in the neonate likewise are overlooked frequently and may be similar to those caused by other congenital infections. Once the diagnosis is suspected, treatment should be started immediately, and diagnostic procedures should be carried out rapidly and aggressively.

The clinical manifestations vary, probably depending on the size of the infecting dose of bacilli and the site and size of the caseous lesions.^{400,445} In many of the reported cases, tuberculosis disease was discovered only at autopsy.²⁶² Symptoms usually appeared during the second week of life and included loss of appetite and failure to gain weight, fever, nasal or ear discharge, cough, bronchopneumonia, jaundice,

hepatomegaly, and splenomegaly occurring later.⁷⁶ Wasting has been noted frequently and, in one case, clearly was shown to be caused by hypoadrenocorticism.⁴²⁶

Because the result of the tuberculin skin test very rarely is positive in infants, demonstration of tubercle bacilli in gastric washings, middle ear fluid, lymph node biopsy specimens, skin biopsy specimens, bone marrow aspirate, endotracheal aspirate, or lung biopsy specimens is essential.²²⁶ Examination of the placenta for organisms or characteristic histopathologic changes can be extremely helpful and should be done when tuberculosis is diagnosed in the mother around the time of delivery. Successful treatment of congenital tuberculosis has been reported by several investigators, although clinical response may be very slow, and extensive calcification of the lungs, liver, spleen, and muscles may result.^{298,302,445,590,603}

Tuberculosis in Adolescents

Tuberculosis in adolescents has become relatively more important as the incidence of infection in childhood has lessened.^{143,380,586} Logically, it should be considered in two ways: first, tuberculosis acquired as an initial infection during the adolescent years and, second, tuberculosis infection acquired in early life and reactivated during adolescence.^{384,447} In actual practice, separating the two often is difficult or impossible, and most clinical reports and studies do not do so.

Tuberculosis in adolescents may occur exactly as it does in young children, or a classic primary complex may progress rapidly to chronic pulmonary tuberculosis while the hilar lymph node involvement characteristic of childhood tuberculosis remains present. The Medical Research Council in 1963 published a report of 504 cases of tuberculosis in adolescents, including 316 cases of pulmonary tuberculosis, 44 cases of pleural effusion, 44 with hilar lymph node enlargement, 6 cases of miliary and 5 of meningeal tuberculosis, 13 with bone and joint disease, and 8 with genitourinary tuberculosis. In a series of cases of primary tuberculosis in adults, Stead⁶¹⁵ included 11 adolescents, 5 with simple primary tuberculosis, 5 with pleurisy and effusion, and 1 with progressive pulmonary tuberculosis.

From the extensive clinical experience of Lincoln and Sewell³⁵³ and others, several observations emerge. Tuberculosis infection in early infancy rarely leads to pulmonary tuberculosis in adolescence, perhaps because it has several years in which to heal, whereas tuberculosis infection acquired after 7 years of age and, in particular, acquired after 10 years of age is likely to progress. When *M. tuberculosis* is acquired during adolescence, chronic pulmonary tuberculosis may develop within 1 to 3 years. Moreover, the risk for acquiring pulmonary tuberculosis is two to six times greater for adolescent girls than for adolescent boys. In both sexes, the adolescent growth spurt is the time of greatest risk. The work of Johnston²⁸⁷ suggests that the depressant effect of puberty on calcium and nitrogen retention, at least in girls, may be correlated with the failure of tuberculosis infection to heal.

While clinical manifestations may overlap with those of younger children, psychosocial factors impacting adolescents are unique. The treating clinician must (without caregivers in the room) discuss use of illicit and prescription drugs and alcohol use, as well as recommending alternatives to oral contraceptives to the sexually active young woman who will be receiving rifamycin. As many adolescents with intrathoracic tuberculosis may be contagious, certain infection control considerations are present for these patients that are not found in younger children: respiratory isolation while in the community; missed school or work; and the attendant depression that often stems from this social isolation.

Tuberculosis and Pregnancy

In the era before chemotherapy, whether pregnancy and tuberculosis affected each other adversely was an ongoing controversy. Since the advent of chemotherapy, however, the prognosis has improved greatly.¹⁹⁶ The main problems now are serious unrecognized tuberculosis in a pregnant woman, sometimes with a fatal outcome, and serious unrecognized disease in her infant. Another problem is whether pregnancy influences the risk for progression of tuberculosis infection to disease; the data are conflicting. Tuberculin skin testing probably is valid during pregnancy; chest radiographs (with shielding) should be obtained for

all tuberculin-positive pregnant patients. Therapy, when indicated, can safely include isoniazid (which crosses the placenta but apparently without ill effects), rifampin, and ethambutol. The safety of pyrazinamide in pregnancy has not been established, but a growing number of experts recommend it because anecdotal data have not shown it to be harmful to the mother or fetus. Streptomycin, because of fetal ototoxicity, is not recommended.⁵⁹⁴ However, one study of seven pregnant women with multidrug-resistant tuberculosis showed no adverse effects on their neonates when mothers were treated with second-line drugs, including aminoglycosides.^{169,574} Mothers receiving antituberculosis therapy can safely breast-feed; the drugs are found in milk at very low concentrations.⁵⁹⁵

Tuberculosis and Human Immunodeficiency Virus Infection

In adults infected with both HIV and *M. tuberculosis*, the rate of progression from asymptomatic infection to disease is increased greatly.⁵³⁸ The clinical manifestations of tuberculosis in HIV-infected adults are typical when the CD4⁺ cell count is higher than 500/mm³. As the CD4⁺ cell count falls, manifestations become "atypical." Extrapulmonary foci occur in as many as 60% of profoundly immunocompromised patients.²⁹ In up to one-fourth of children, intrathoracic and extrathoracic tuberculosis may occur simultaneously.²⁴³ Pulmonary cavities are rare findings; lower lobe infiltrates or nodules often accompanied by thoracic adenopathy are common occurrences, especially if the patient's tuberculosis infection is recent. Focused assessment with sonography for HIV/TB (FASH) was developed to help diagnose pleural and pericardial effusions and extrathoracic TB in HIV-infected children and adults. FASH can demonstrate intraabdominal lymphadenopathy, splenic abscesses, and hepatic lesions.²³⁷

Many HIV-infected patients have a nonreactive tuberculin skin test. IGRAs have been poorly studied in this patient population, and studies have found poor correlation between IGRAs and TSTs and between IGRAs and TB risk factors.^{520,521} Sputum is less likely to be produced or to contain visible acid-fast organisms on stained smears; more invasive procedures, such as bronchoscopy, often are required to isolate *M. tuberculosis* and to rule out other causes of opportunistic lung disease.³⁸⁷ Malabsorption of antituberculosis drugs in HIV-infected patients can lead to prolonged symptoms and disease.⁴⁹⁰

When tuberculosis develops in HIV-infected children, the clinical features tend to be fairly typical of childhood tuberculosis in immunocompetent children, although the disease often progresses more rapidly and the clinical manifestations are more severe.^{55,100,109,181,183,253,309,429,474,652} Many children have sizeable pulmonary radiographic findings with minimal respiratory signs or symptoms. An increased tendency for extrapulmonary disease may be noted. Nonspecific signs and symptoms,⁶⁹² overlap in symptomatology with other opportunistic infections, and higher rates of culture-positive patients with negative radiographs make the diagnosis challenging. Consequently, studies evaluating the utility of symptom-based scoring systems have shown discrepant results.^{181,381,488} Establishing the diagnosis can be very difficult; a diligent search for an infectious adult in the child's environment may yield the best clues to the correct diagnosis.³¹⁴ Recurrent disease and relapse occur more frequently in HIV-infected children.⁵⁴⁵ The prognosis generally is good if tuberculosis disease is not far advanced when the patient is diagnosed and appropriate antituberculosis drugs are available.²⁴³

Tuberculosis and Immune Reconstitution Inflammatory Syndrome

The introduction of highly active antiretroviral therapy (HAART) into regions where tuberculosis is prevalent has had a profound effect on the epidemiology and clinical expression of both diseases. One manifestation may be immune reconstitution inflammatory syndrome (IRIS). IRIS manifestations can include either worsening of tuberculosis symptoms while on effective therapy (paradoxical IRIS) or new-onset tuberculosis symptoms after initiation of HAART (unmasking IRIS).^{408,610} Sometimes it is difficult to tell if a deterioration in the clinical course of a patient with an opportunistic infection who is started on HAART is due to IRIS, poor compliance with treatment for the opportunistic infection, or drug resistance.³³³⁻³³⁵ Consensus case definitions were created in 2008 to help differentiate among these diagnostic possibilities.

Paradoxical IRIS is defined for patients diagnosed with tuberculosis before starting HAART and who showed an initial response to antituberculous medication. Major criteria include new or enlarging lymph nodes or focal tissue involvement, central nervous system findings, serositis, or new or worsening radiographic findings. Minor criteria include new or worsening constitutional or respiratory symptoms or new or worsening abdominal pain accompanied by peritonitis, organomegaly, or intraabdominal lymphadenopathy. At least one major or two minor criteria are needed for diagnosis. Unmasking IRIS is defined in patients not receiving tuberculosis treatment when HAART is initiated who then develop tuberculosis with evidence of substantial inflammation (e.g., tuberculous lymphadenitis, pulmonary tuberculosis accompanied by respiratory failure).⁴⁰⁸

There continues to be a paucity of data on IRIS in HIV-infected children. One systematic review included 303 cases of TB-IRIS, 90% of which were unmasking IRIS, but noted few data on risk factors, immunopathogenesis, or treatment.³⁵⁷ Factors suggesting IRIS are temporal association (within 4 months of starting HAART), unusual clinical manifestations, unexpected clinical course, exclusion of alternative explanations, evidence of preceding immune restoration (rise in CD4 lymphocyte count), and fall in HIV viral load. In adults, the risk for developing IRIS in patients with tuberculosis who are started on HAART is greatest if they have extrapulmonary tuberculosis, high initial HIV viral loads and low CD4 lymphocyte counts, and rapid response to HAART.^{56,433} One metaanalysis showed that paradoxical IRIS developed in 16% percent of adults with tuberculosis.⁴³³ Although the risk for IRIS is higher when HAART is initiated shortly after antituberculosis medications are begun, most reactions are mild and the survival benefit in patients receiving HAART outweighs the risk for IRIS.^{50,291}

Published reports of IRIS in children have been rare,^{290,441,467,500,693,720} although anecdotal evidence from pediatric acquired immune deficiency clinics in Africa suggest it is becoming common as HAART is introduced to more children with HIV infection. One study indicated that IRIS was seen in almost 40 percent of HIV-infected children and was more common in boys than girls and more common in children 5 to 12 years of age, and that unmasking IRIS comprised more than three fourths of cases.⁴⁶⁷ Other studies have shown lower incidence of IRIS,^{500,693} but the finding that IRIS is more common in children with disseminated disease and malnutrition has been documented in multiple studies.^{467,693} IRIS in children has been associated with nontuberculous mycobacteria,⁵⁰⁰ disseminated viral^{500,693} or fungal infections,⁴⁶⁷ bacterial pneumonia,⁴⁶⁷ and previous BCG vaccination.^{320,501,576} The finding that IRIS occurs in children with tuberculosis and HIV infection who receive HAART is not surprising. For decades, so-called paradoxical reactions have been described in HIV-uninfected children with tuberculosis after antituberculosis therapy is started. The most common manifestations are fever, cough, new skin lesions, enlarging lymph nodes in the thorax or neck, and appearance or enlargement of tuberculomas in the brain, with or without accompanying meningitis.^{408,467} The risk for unmasking IRIS appears to be highest in the first 3 months after initiation of HAART.²⁷

IRIS also can be seen in HIV-uninfected children. One study in HIV-uninfected children showed that unexpected deterioration while on therapy was seen in almost 15% of children, most commonly manifest as enlarging intrathoracic lymphadenopathy. In this cohort, IRIS was more common in children with multiple sites of disease and in children whose weight was in the lowest quartile.⁶⁵⁰

The best management of IRIS is unknown. As with paradoxical reactions that cause tissue damage or obstruction, corticosteroids may be beneficial to "quiet" the local immune response, although no randomized clinical trials have been reported. Less severe reactions may respond to nonsteroidal antiinflammatory drugs. The high frequency of IRIS associated with tuberculosis has led some experts to recommend delay of HAART until appropriate (for drug susceptibility pattern) antituberculosis chemotherapy has been given for at least 2 months.³⁴⁶ No consensus on this approach has been reached, however, and data from children may indicate that they are more likely to die of complications of HIV than of tuberculosis when they are dually infected.²⁴³

DIAGNOSIS

In the developing world, the only way that children with tuberculosis disease are discovered is passively, when they have a profound illness that is consistent with a manifestation of tuberculosis. Having an ill adult contact is an obvious clue to establishment of the correct diagnosis. The only available laboratory test usually is an acid-fast smear of sputum, which the child rarely produces. In many regions, chest radiography is not available. To aid in establishing the diagnosis, a variety of scoring systems based on available tests, clinical signs and symptoms, and known exposures have been devised.^{413,699} No single clinical scoring system has been validated. Sensitivities and specificities tend to be low, resulting in both overdiagnosis and underdiagnosis of tuberculosis. Sensitivity is quite low in HIV-infected children.^{307,390,413} Finally, differing prevalences of tuberculosis can skew predictive values.

In industrial countries, children with tuberculosis usually are discovered in one of two ways.^{167,311,540} Obviously, one way is to consider tuberculosis as the cause of a symptomatic illness.⁵²⁹ Discovering an adult contact with infectious tuberculosis is an invaluable aid to establishing the diagnosis; the “yield” from a contact investigation usually is higher than that from cultures from the child.³⁷ Culture from the infectious adult case may yield the only drug susceptibility results for the child because cultures from children with tuberculosis frequently are negative. Children often are the first in the family to be diagnosed with tuberculosis, potentially owing to different thresholds for seeking medical attention for children and adults, and more rapid onset of severe manifestations in young children. A negative exposure history does not rule out tuberculosis in a child. The yield of contact investigations is higher for children than adults, owing to the former’s more limited social network. Yield of contact investigations may be lower in foreign-born children, whose source cases may still reside in their country of origin.⁵⁶⁸ The second way is to discover a child with pulmonary tuberculosis during the contact investigation of an adult with tuberculosis.^{392,421,598,629,631} Typically, the affected child has few or no symptoms, but investigation reveals a positive tuberculin skin test result and an abnormal chest radiograph. In some areas of the United States, as many as 50% of children with pulmonary tuberculosis are discovered in this manner, before significant symptoms have begun.

The recent use of molecular epidemiology techniques has shown, however, occasional discordance between the isolate from the child and that from the presumed source, meaning that the real source of transmission to the child is undiscovered.^{710,718} It is less common to find tuberculosis disease in a US-born child as the result of a community- or school-based tuberculin skin testing program, although foreign-born children with tuberculosis may be found in this manner.^{168,487}

Tuberculin Sensitivity and the Skin Test

Sensitization to tuberculin is induced by infection with living tubercle bacilli. Specific tuberculin sensitivity to either *M. tuberculosis* or other mycobacteria can be transferred in humans by injection of lymphocytes from sensitized donors and also by injection of certain purified mycobacterial protein antigens. Sensitization to tuberculin as a result of infection with *M. tuberculosis* tends to persist undiminished for life.^{180,230,256}

The time of appearance of sensitivity in animals after infection with *M. tuberculosis* has occurred depends on the number of tubercle bacilli in the infective dose and on the virulence (i.e., the rate of multiplication of the organisms), and such is also likely to be the case in humans.³⁰ For all practical purposes in humans, tuberculin reactivity seems to appear in 3 to 6 weeks, and occasionally as long as 3 months after initial infection. The size of the induration depends on the amount of tuberculin protein injected and the availability of sensitized T lymphocytes in sufficient number. The size of the induration seems to depend on at least two additional factors: the local behavior of the skin (the disappearance time for wheals of normal saline solution, the so-called Aldrich-McClure test, is accelerated during fever, pregnancy, cachexia, and extreme malnutrition) and the number of actively multiplying tubercle bacilli in the body. That still other factors must be involved is clear because 10% to 20% of immunocompetent patients with proven tuberculosis are tuberculin negative during initial disease, with tuberculin sensitivity often regained during treatment.⁴⁹⁵

Falsely negative tuberculin skin tests can be seen in a number of circumstances. Temporary desensitization to tuberculin occurs most strikingly during wild-type measles and has been studied carefully. Full reactivity diminished during the incubation period and returned within approximately 1 month after appearance of the exanthem.²³⁸ Influenza and administration of influenza and measles vaccines tend to depress sensitivity but rarely suppress it entirely.^{319,730} Whether other viral diseases and vaccines regularly are less active in this regard and what the important factors may be are not known.⁴⁰ If a temporary desensitizing effect occurs in bacterial infections such as scarlet fever, it probably depends on factors such as hyperthermia and dehydration. Corticosteroids,^{58,368,548} HIV infection,^{376,506} adrenocorticotrophic hormone,⁵³³ nitrogen mustard,⁶⁹⁴ and irradiation¹³⁷ diminish tuberculin reactivity, perhaps simply by inducing lymphopenia.⁶¹²

False-positive results of tuberculin skin tests also are seen. That degrees of sensitivity to *M. tuberculosis* are induced by nontuberculous mycobacteria also is clear.²²⁷ Previous receipt of BCG vaccine can cause increased reactivity to tuberculin, but the association is weaker than many clinicians suspect.^{10,80,364,431,563} Less than 50% of infants given BCG vaccination have a reactive tuberculin skin test at 9 to 12 months of age, and the great majority will have a nonreactive skin test by the time they are 5 years of age. Older children and adults who receive BCG vaccination have a reactive skin test and keep it longer, but by 10 to 15 years after vaccination most individuals have lost tuberculin skin test reactivity.^{119,411,536} However, a Chinese population-based cohort of persons 5 years old and older found significantly higher rates of TST positivity (15–42%) than IGRA positivity (13–20%).²⁰⁴ This raised concerns that the prevalence of TB infection was being overestimated by the TST. Repeated administration of BCG vaccine can maintain tuberculin reactivity.²⁶⁹ Repeated tuberculin skin tests in a person sensitized previously by BCG vaccination, infection with *M. tuberculosis*, or probably infection by an environmental mycobacterium may increase the reaction to subsequent tuberculin skin tests (called the booster phenomenon).^{44,298,562,656}

The Mantoux test is the reference test. A graduated syringe and a 26- or 27-gauge needle are used to inject 0.1 mL of PPD into the most superficial layer of the epidermis of the forearm, which raises an immediate wheal (Fig. 96.12). Under optimal circumstances, the needle should not be withdrawn for a few seconds to minimize leakage. If there is leakage or if the injection was too deep and no wheal is noted, the skin test should be repeated at least 5 cm from the original site. The reference test uses a dose of 5 tuberculin units of PPD-S or 2 units of RT-23. The reading should be made at 48 to 72 hours, with the forearm slightly flexed. Any induration (not erythema) should be measured, preferably with calipers, and the diameter at right angles to the axis of administration recorded in millimeters. Any blistering or ulceration also should be noted. Use of the words “negative” and “positive” should be avoided because interpretation can change as more

FIG. 96.12. A useful technique for performing a Mantoux tuberculin skin test on a child. The needle is applied perpendicular to the long axis of the arm to attain better control.

epidemiologic information becomes known. No study has demonstrated that parents or patients can read positive skin test results accurately, but that they may not correctly interpret or report positive results has been well documented.^{106,106,220,254,470} Two studies have demonstrated that pediatric care providers tend to under-read Mantoux tuberculin skin tests.^{72,276} Several studies have shown great variability in readings of Mantoux tests.^{34,79,301,470} Such variability can be minimized only by ongoing training of both testers and readers and by concentrating the responsibility of testing and reading to a small number of trained individuals.

The importance of the tuberculin test cannot be overemphasized as the main criterion for diagnosis of tuberculosis infection in an individual child. Only rarely is the tuberculin test response negative in an infected child, usually as a result of anergy from overwhelming infection, from viral infection, from HIV infection, from the use of immunosuppressive drugs, or because of factors not yet understood.⁶²¹ Anergy in tuberculosis can be selective for tuberculin; results of “control” skin tests may be positive but the Mantoux test result negative in a child with tuberculosis disease.⁶¹⁴ The utility of candidal or tetanus controls is limited and they are not recommended. In lieu of controls, clinicians need to be cognizant of the decreased sensitivity of the test in young children and immunocompromised patients.

The Mantoux test has a sensitivity and specificity of only approximately 95% at 10 mm of induration.²⁶⁰ When a test with these characteristics is applied to a population with a 90% prevalence of tuberculosis infection, the positive predictive value of the skin test is 99%, an excellent result. However, if the same test is applied to a population with only a 1% prevalence of infection, the positive predictive value drops to 15%; 85% of the “positive” results are false-positive findings created by biologic variability, nonspecific reactions, and infection with environmental mycobacteria. These false-positive results lead to unnecessary treatment, cost, and anxiety for the patient, family, and clinician. In short, the low sensitivity and specificity of the tuberculin skin test render the test undesirable for use in persons from low-prevalence groups. The trend in the United States is to reduce or to eliminate routine testing of low-risk children but to target children with specific risk factors for one-time or periodic tuberculosis skin testing.^{12,90,422}

In lieu of mass screening using tuberculin skin tests, children should be screened by history. Several recently published studies have shown that a questionnaire can be used in the United States to identify children with significant risk factors for tuberculosis infection, who then can receive a tuberculin skin test.^{201,361,471,527} Factors that consistently correlate with having a positive tuberculin skin test result include contact with a case of tuberculosis, other family members with a positive tuberculin skin test result, and foreign birth or extensive travel to a high-prevalence country.⁵⁵¹ The predictive value of these questions may be diminished in high-prevalence areas. Having a parent born in a high-incidence nation is a risk factor for a child having TB disease⁷⁰⁵; however, the association of parental foreign birth on TB infection is unclear.

The CDC and the American Academy of Pediatrics (AAP) have recommended varying the size of induration considered positive in various groups, according to their risk factors (Table 96.6). This is an attempt to increase sensitivity in children most likely to have rapid progression of asymptomatic tuberculosis infection to disease and to increase specificity in persons with no known risk factors for tuberculosis. In general in the United States, previous receipt of BCG vaccine should not influence interpretation of the initial tuberculin skin test of a child.²⁸⁶

Advances in interferon- γ release assays (IGRAs) in molecular biology and genomics have led to use of alternatives to the tuberculin skin test.^{473,609} Two in vitro formats have been developed that measure interferon- γ release by sensitized lymphocytes after stimulation by *M. tuberculosis* antigens.⁶¹¹ Both formats use proteins—early secreted antigen target 6, culture filtrate protein (CFP)-10—that are found on *M. tuberculosis* and only a few species of nontuberculous mycobacteria (*M. kansasii*, *M. marinum*, *M. szulgai*, and *M. flavescens*) but not on the bacilli BCG or the *M. avium* complex. The first test licensed in the United States was QuantiFERON-TB and includes an extra antigen (TB7.7). The test measures whole-blood interferon production. The second format licensed in the United States is the enzyme-linked immunospot (T-SPOT.TB), which measures the number of mononuclear cells that produce interferon.

TABLE 96.6 Amount of Induration in Reaction to a Mantoux Tuberculin Skin Test Considered Positive (Indicating Probable Infection With *Mycobacterium Tuberculosis*)

Reaction Size	Risk Factors
≥ 5 mm	Contact with infectious cases Abnormal chest radiograph HIV infection or other immunocompromise
≥ 10 mm	Birth or previous residence in a high-prevalence country Residence in long-term care or corrections facility Certain medical risk factors: diabetes mellitus, silicosis, renal disease Occupation in health care field, exposure to patients with tuberculosis Member of a local high-risk group Close contact with a high-risk adult (except health care workers) Age <4 y
≥ 15 mm	No risk factors

Both formats of IGRAs have been studied extensively in adults.⁴⁷³ Sensitivity in HIV-uninfected adults with disease has ranged from 73% to 96%,^{412,472} and reported specificities range from 86% to 99%.^{150,564} In HIV-infected adults with disease, sensitivity and specificity have ranged from 30% to 92% and 52% to 76%, respectively.^{105,412} One metaanalysis of IGRA performance in HIV-uninfected adults with infection demonstrated specificities ranging from 98% to 100%.¹⁴⁹ There is some evidence that the T-SPOT.TB is less affected by immunosuppression in HIV-infected adults than the QuantiFERON.^{84,472}

In many clinical situations, these tests have a higher specificity than that of the TST, better correlation with surrogate measures of recent exposure to *M. tuberculosis* in low-incidence settings, and less cross-reactivity than does the TST because of previous BCG vaccination [Table 96.7]. Like the tuberculin skin test, interferon release assays cannot differentiate between tuberculosis infection and disease. Two clear advantages of the interferon release assays are the need for only one patient encounter (vs. two with the tuberculin skin test) and the lack of possible boosting of the result, because the patient is not exposed to any biologic material. It is unclear to what degree an IGRA can be boosted by a preceding tuberculin skin test. One metaanalysis reported substantial within-subject variation in IGRAs before and after tuberculin skin testing, but the frequency varied dramatically (16–80%).⁶⁷⁶ Two more recent studies did not demonstrate boosting.^{518,539} Although the potential risk for boosting can be avoided by obtaining the IGRA before or at the same time as placing the tuberculin skin test, prior receipt of a tuberculin skin test is not a contraindication to IGRA use.

There are fewer pediatric studies of IGRAs but several metaanalyses of the available studies have been performed.^{369,375,634} Sensitivity in children with microbiologically confirmed or all children diagnosed with tuberculosis disease (clinically diagnosed disease and microbiologically confirmed) has ranged from 53% to 100% and from 53% to 94%, respectively. However, low sensitivity of the IGRAs in children with microbiologically confirmed disease may be due, in part, to the immunosuppression caused by the disease; these children also are more likely to have a negative tuberculin skin test. As with the tuberculin skin test, a negative IGRA result never rules out tuberculosis disease.^{355,552}

The performance of IGRAs is limited in certain groups by an increased rates of indeterminate results, most often caused by failure of the positive control of the test. Immunocompromised children, including those with cancer^{81,616} and HIV infection,^{122,292,375} are more likely to have indeterminate test results,^{234,377} as are children younger than 2 years of age.²⁹² Whereas some studies have shown no association between indeterminate results and age,⁴⁸⁴ others have reported high rates of indeterminate test results in children younger than 4 or 5 years of age.^{42,125} It appears that technical

TABLE 96.7 Suggested Uses of TST and IGRAs in Children

Preferred Test	Scenario
TST preferred	Children age <5 y ^a
IGRA preferred, TST acceptable	Children age ≥5 y who have received the BCG vaccine Children ≥5 y who are unlikely to return for TST reading
Both the TST and an IGRA should be considered	Initial and repeat IGRA results are indeterminate/invalid Initial test (TST or IGRA) is <i>negative and</i> : There is clinical suspicion of TB disease ^b The child has a TB risk factor and is at high risk of progression and poor outcome (especially therapy with an immunomodulating biologic agent, such as a tumor necrosis factor- α antagonist) ^b Initial TST is <i>positive and</i> : Patient is ≥5 y and has a history of BCG vaccination Additional evidence is needed to increase adherence with therapy

From Starke JR and the Committee on Infectious Diseases, American Academy of Pediatrics. Interferon- γ release assays for diagnosis of tuberculosis infection and disease in children. *Pediatrics*. 2014;134:e1763–e1773.

^aSome experts will use an IGRA in children aged 2 to 4 y, especially if they have received a BCG vaccine but have no other significant risk factors. Most experts do not use IGRAs in children age <2 y because of the lack of data in this age group and the high risk of progression from infection to disease.

^bEither the TST or the IGRA result being positive would be considered significant in these groups.

IGRA, Interferon- γ release assay; TST, tuberculin skin test.

factors such as inadequate shaking of the test tube contribute significantly to indeterminate results.^{68,472} Helminthic infections have also been associated with indeterminate results,⁶⁵⁴ a particular concern when screening international adoptees.⁵⁹⁹

Determining performance for children with tuberculosis infection is more challenging, because there is no reference standard. One proxy is degree of exposure to a documented source case. Sensitivity and specificity for infection have ranged from 90% to 92% and 91% to 95%, respectively.³⁶⁹ Concordance between results from the tuberculin skin test and IGRAs vary widely. Although high concordance (>90%) has been reported from low-prevalence settings where BCG is not used, concordance decreases in BCG-immunized children.^{42,125,369} IGRAs appear to correlate more closely than tuberculin skin tests for BCG-vaccinated children identified in contact investigations.^{192,521} However, data are conflicting, and other studies have shown similar performance for the tuberculin skin test and IGRAs for the diagnosis of pediatric tuberculosis infection.⁵ Some studies have demonstrated a decrease in the sensitivity of both the IGRAs and the tuberculin skin test with decreasing age and in HIV-infected children,³⁷⁵ while other studies have demonstrated good performance in these two groups.^{51,378}

The American Academy of Pediatrics (AAP) has suggested that IGRAs be used with caution in children younger than 5 years of age given the relative paucity of data for this age group.^{97,611} The main reason for caution is that sensitivity is paramount for infants and toddlers who have a higher risk of progression to disease if they have untreated tuberculosis infection. However, many experts use the IGRAs in children down to 2 years of age. An optimal use for these assays—when one wants to maximize specificity—is in the BCG-immunized older child (≥5 years of age) who lacks tuberculosis risk factors aside from birth in a high-prevalence nation. Another use may be for a child whose family is reluctant to treat infection based on a tuberculin skin test result alone or when there may be difficulty having the child return for the reading of the tuberculin skin test. In children with suspected disease, or for children with a high risk of progression to disease (such as those

about to undergo significant immune suppression with drug therapy), obtaining both a tuberculin skin test and one or both IGRAs provides maximum sensitivity. Because most studies have not shown a consistent, significant difference between the two IGRAs, the CDC and the AAP recommend that the assays may be used interchangeably.⁹⁷

Given the brief period of time during which IGRAs have been used, some questions remain unanswered, including the dynamics of IGRAs—when they become positive after exposure to a person with tuberculosis disease, how long they remain positive, and the degree to which conversions and reversions occur on therapy. These questions may be best answered with longitudinal studies.

Diagnostic Mycobacteriology in Children

The demonstration of acid-fast bacilli in stained smears of sputum is presumptive evidence of pulmonary tuberculosis in most patients.⁵³¹ However, children have paucibacillary disease. Gastric washings, which often are used in lieu of sputum, can be contaminated with nonpathogenic oral acid-fast organisms. Tubercle bacilli in CSF, pleural fluid, lymph node aspirate, and urine are sparse; thus, only rarely are direct-stained smears for tubercle bacilli of any use in pediatric practice.⁶²⁶ Cultures for tubercle bacilli are of great importance, not only to confirm the diagnosis but increasingly to permit testing for drug susceptibility. If culture and drug susceptibility data are available from the associated adult case and the child has classic features of tuberculosis (positive skin test result, consistent abnormal chest radiograph), obtaining cultures from the child adds little to management. In many low-incidence countries, a child usually will have contact with only one adult with potentially contagious TB. This is a poor assumption in hyperendemic areas, and cultures on the child should still be obtained. Similarly, cultures in the child should be attempted in children with suspected TB disease if the associated adult case has drug-resistant tuberculosis, as different drug susceptibility profiles would alter management substantially.

Painstaking collection of specimens is essential for diagnosis of children because fewer organisms usually are present than in adults.⁵⁷⁵ Yield may be increased by obtaining multiple specimens from the same site, or by obtaining specimens from different locations (e.g., urine samples and gastric aspirates).⁶⁵³ Gastric lavage should be performed in the very early morning, when the patient has had nothing to eat or drink for 8 hours and before the patient has a chance to wake up and start swallowing saliva, which could dilute the bronchial secretions that were brought up during the night and made their way into the stomach. The stomach contents should be aspirated first. No more than 50 to 75 mL of sterile distilled water (not saline) should be injected through the stomach tube and the aspirate added to the first collection. The gastric acidity (poorly tolerated by tubercle bacilli) should be neutralized immediately. Concentration and culture should be performed as soon as possible after collection. However, even with optimal, in-hospital collection of three early-morning gastric aspirate samples, *M. tuberculosis* can be isolated from only 30% to 40% of children and 70% of infants with pulmonary tuberculosis.^{71,614,669} One review of 31 studies on gastric aspirate yield in children found that smear-positivity was seen in 1% to 21% and culture positivity rates of 7% to 75%, depending on the inclusion criteria for the study.⁶²⁵ Higher rates of smear and culture positivity were seen in studies where children with longer symptom duration, positive TSTs, or specific radiographic findings were included.

Sputum induction is an alternative to gastric aspiration. Sputum induction is an outpatient procedure that can be performed in clinic settings⁴²⁴ and requires the child to be fasting for only 3 hours. A nebulized treatment with a β agonist is given, followed by a nebulized treatment with hypertonic saline. The β agonist decreases the risk for bronchospasm occasionally seen with hypertonic saline. Saline increases the tussive force in children (even those who had no cough initially). As children begin to cough up secretions, the child's oropharynx is suctioned. One study from a high-prevalence nation showed that one specimen obtained via sputum induction had the same smear and culture yield as three gastric aspirates.^{273,722} Sputum induction in HIV-infected and HIV-uninfected adults had the same diagnostic yield as specimens obtained via bronchoscopy.¹²¹ In most studies, the yield of *M. tuberculosis* from bronchoscopy specimens has been lower than from properly obtained gastric aspirates.^{1,99}

The string test is a less invasive approach to diagnosing childhood tuberculosis. This procedure, originally designed for enteric pathogens such as *Giardia* and *Helicobacter*, entails the child swallowing a gelatin capsule containing a coiled absorbent string. One end is taped to the cheek before the child swallows the pill. After 2 hours, the string is gently removed via the mouth and placed in sterile normal saline. While best studied in adult patients, one pediatric study found comparable smear (4–5%) and culture (9%) in for string test and sputum induction.⁴⁴⁰ One obvious limitation is the need for a child to be able to swallow an intact pill, which has limited data collection predominantly to school-aged children.

CSF, pleural fluid, and synovial fluid (as much fluid as possible should be collected) usually are centrifuged, and the sediment is used for stained smear and culture. An overnight urine specimen should be obtained in the early morning and taken immediately to the laboratory for processing because the organisms tolerate the low pH of urine poorly. Lymph node aspirates and biopsy tissue can be inoculated directly into a fluid medium such as Middlebrook 7H9.

Staining and examination of smears as well as inoculation of special media, incubation in a carbon dioxide environment, strain differentiation based on many cultural characteristics, and drug susceptibility testing require equipment, skills, and experience beyond those available in the usual clinic or hospital laboratory.²⁴² Thus, most laboratories depend on regional or reference laboratories for procedures beyond their scope.

Traditional drug susceptibility testing ordinarily is performed for isoniazid, rifampin, ethambutol, and streptomycin. For many years, pyrazinamide susceptibilities were not routinely performed owing to testing complexities. This made the diagnosis of *Mycobacterium bovis* (which is inherently pyrazinamide resistant) challenging. Recently, laboratory advances have resulted in pyrazinamide susceptibility testing being more widely available. Drug susceptibilities are performed using one of two systems: agar proportions and growth in liquid media. For agar proportions, the organism is inoculated onto two plates: one with a specified concentration of an antibiotic and one that is drug free. The proportion of colonies on each plate is compared, and if there is more growth on the antibiotic plate, the isolate is considered resistant to that drug. For automated liquid media systems (e.g., BACTEC), the isolate is inoculated into vials with and without antibiotic. If the drug-containing vial grows faster than or at the same rate as the drug-free vial, then the isolate is considered resistant to that drug. Susceptibilities to other medications can be requested if the isolate is resistant to first-line medications.

Pyrosequencing, detecting pyrophosphate release during DNA synthesis, has been used to detect mutations associated with resistance to several first- and second-line medications. One advantage is the ability of pyrosequencing to detect mutations in multiple loci in several isolates in real time.¹⁹⁰

Nucleic Acid Amplification

The main form of nucleic acid amplification studied in children with tuberculosis is PCR, which uses specific DNA sequences as markers for microorganisms.^{379,423} Various PCR techniques, most using the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms,^{12,85} have a sensitivity and specificity of more than 90% in comparison to sputum culture for detecting pulmonary tuberculosis in adults. Other advantages include the ability to detect even low organism burdens, a particular consideration in children with paucibacillary disease; rapidity of results and decreased time to initiation of therapy and patients lost to follow-up; ability to differentiate between *M. tuberculosis* and nontuberculous mycobacterial species; and potentially diminished biosafety requirements.⁴⁵⁰ Disadvantages include diminished sensitivity in patients with smear-negative disease; expense of equipment; variation in test performance even among reference laboratories^{454,704}; and concern for cross-contamination. One study in Peru found that cross-contamination was so common that PCR positivity was as likely to be seen in well controls as from suspected cases.⁴⁵⁸

Evaluation of PCR in childhood tuberculosis has been limited. Compared with a clinical diagnosis of pulmonary tuberculosis in children, the sensitivity of PCR has varied from 25% to 83% and specificity has varied from 80% to 100%.^{423,457,482,549,589} PCR of stool had a sensitivity

of 30% to 40% and a specificity of 100% in children with pulmonary tuberculosis,⁷⁰⁹ offering a noninvasive diagnostic modality. PCR of gastric aspirates may be positive in a recently infected child even when the chest radiograph is normal, demonstrating the occasional arbitrariness of the distinction between tuberculosis infection and disease in children. PCR may have a useful but limited role in evaluating children for tuberculosis. A negative PCR analysis never eliminates tuberculosis as a diagnostic possibility, and a positive result does not confirm it. PCR may be particularly helpful in evaluating immunocompromised children with pulmonary disease, especially those with HIV infection, although published reports of its performance in such children are lacking. PCR also may aid in confirming the diagnosis of extrapulmonary tuberculosis, but only a few reports have been published.^{214,374,415}

Xpert TB/RIF is a real-time PCR assay for *M. tuberculosis* that simultaneously detects rifampin resistance. Rifampin resistance is used as a proxy for MDR-TB, because rifampin monoresistance is uncommon.¹⁶⁶ Rifampin mutations, in contrast to isoniazid mutations, cluster on a small part of the mycobacterial genome and synonymous mutations are rare, facilitating molecular detection of drug resistance. This assay uses a self-contained cartridge system and is not as operator dependent as traditional PCR. A metaanalysis conducted in 2013 included over 2600 children. Specificity was excellent (98%); pooled sensitivity was only 66%, but this was still a higher sensitivity than smear microscopy (which has reported sensitivities of 30–40%).⁴⁴⁹ Sensitivity was higher among smear-positive (95–96%) than smear-negative (55–62%) patients. This study found no difference in performance between HIV-infected and -uninfected children.⁷¹³ A metaanalysis from 2015 compared Xpert TB/RIF to culture; sensitivity of Xpert was 62% and specificity was 98%, which was 36% to 44% higher than the sensitivity for smear microscopy. Xpert's sensitivity in detection of rifamycin resistance was 86%.¹⁴⁷ Although cartridges for the Xpert system are expensive, the self-contained system offers advantages in rapid detection of MDR-TB and the prospect of increasing available diagnostics in settings that lack laboratory infrastructure. However, Xpert does not replace the need for obtaining mycobacterial cultures. Culture remains more sensitive than Xpert^{147,210,713} and the need to identify additional drugs to which the isolate is susceptible is crucial for advancing patient care.

Line probe assays (e.g., GenoType MTBDR_{plus} by Hain) detects mutations conferring resistance to rifamycins (*rpoB*) and low- and high-level resistance to isoniazid (*inhA* and *katG*, respectively). There are few pediatric data for line probe assays; in adults, specificity is excellent (>99%), but sensitivity varied from 57% to 100%.³⁵⁶

In the United States, samples can be sent to the CDC laboratory for molecular detection of drug resistance (MDDR). This PCR-based platform evaluates for mutations that commonly result in resistance to different drugs (e.g., *katG* and *inhA* mutations for isoniazid, *rpoB* mutations for rifamycins, *pncA* mutations for pyrazinamide, *embB* mutations for ethambutol, and *gyrA* mutations for fluoroquinolones). The average turnaround time is 2 days. Sensitivity is highest for *rpoB* and *katG* mutations, where most mutations conferring resistance are found on a specific part of the genome; specificity is excellent.⁷⁵

TREATMENT

Management of Tuberculous Children

Treatment of cavitary tuberculosis in adults is one of the most scientifically accurate areas in all of medicine and one of the finest examples of international professional cooperation in all of history. The ability to quantify the extent of disease and the large numbers of cases of tuberculosis have allowed researchers to address specific questions about optimal drug regimens and doses, duration of therapy, and nonmedical management. Historically, treatment recommendations for children have been extrapolated from data in adults.^{22,53,88,114,249,250,281,578,581} However, during the past 3 decades, a large number of treatment trials for children have been reported, which has led to dramatic changes in the therapeutic approach to childhood tuberculosis.

As recently as the early 1980s, the recommended treatment duration for children with tuberculosis disease was 12 to 18 months. Although these regimens are effective when they are used properly, actual failure rates are high because of poor adherence during the long period of

treatment. Newer regimens often are called short-course chemotherapy because treatment durations as short as 6 months are routinely successful. However, the key to the new approach is not the short duration but the intensive initial therapy with three or more antituberculosis drugs.

Antituberculosis Drugs

Isoniazid is the mainstay of therapy for tuberculosis in children (Tables 96.8 and 96.9). Inexpensive, bactericidal, of low molecular weight and therefore readily diffusible to all tissues in the body,¹⁵⁹ and relatively nontoxic to children, isoniazid is one of the most nearly perfect drugs in the pediatrician's armamentarium. It can be administered orally, intramuscularly, or intravenously. When the drug is taken orally, high plasma, sputum, and CSF levels are reached within a few hours and persist for at least 6 to 8 hours.^{330,463} Because of the slow multiplication of *M. tuberculosis*, the total daily dose can be given at one time. The usual level necessary to inhibit multiplication of tubercle bacilli is 0.02 to 0.05 µg/mL.

Human variation in the acetylation rate of isoniazid to an inactive compound is known to be determined genetically.³⁹⁶ Rapid acetylation occurs more frequently in blacks and Asians than in whites. Although a simple method, specifically the use of a urine sample, now is available

for classifying patients as slow or rapid inactivators of isoniazid, the normal way of coping with the problem in children has been to give a sufficiently large dose of isoniazid to ensure an adequate level even in rapid inactivators.^{393,679}

The principal toxic effects of isoniazid are peripheral neuritis and hepatitis. Peripheral neuritis resulting from competitive inhibition of pyridoxine utilization is a rare event in North American children because both milk and meat are the main dietary sources of pyridoxine.⁴⁸ In some well-nourished children, serum pyridoxine concentrations are depressed by isoniazid but clinical signs are not apparent.⁴⁸⁹ In the case of most children, therefore, the use of supplementary pyridoxine is not necessary. However, in teenagers whose diets may be inadequate, in children from ethnic groups with low milk and meat intake, in HIV-infected children, and in breast-fed infants, pyridoxine supplementation (25 to 50 mg/day) is important. Peripheral neuritis, when it does occur, usually is manifested by "pins and needles" sensations in the hands and feet.

The risk for development of hepatotoxicity from isoniazid, which is rare in children, increases in frequency with age.^{35,83,318,358,439,459,503,601,617} Its cause is unclear.³²² Rapid acetylators are no more susceptible than are slow acetylators.^{184,393} Simultaneous use of alcohol, phenytoin, piperazine, and

TABLE 96.8 Commonly Used Drugs for the Treatment of Tuberculosis Disease in Children

Drug	Dosage Forms	Daily Dose (mg/kg/day)	Twice-Weekly Dose (mg/kg/dose)	Thrice-Weekly Dose (mg/kg/dose)	Maximal Daily Dose
Ethambutol	Tablets: 100 mg, 400 mg	20–25	50	Not recommended for young children 1.5 g if 40–55 kg 2.5 g if 56–75 kg 3 g if >75 kg	2.5 g
Isoniazid ^a	Scored tablets: 100 mg, 300 mg Syrup ^b : 10 mg/mL	10–15 ^b	20–30	15	Daily: 300 mg Twice weekly: 900 mg Thrice weekly: 900 mg
Pyrazinamide	Scored tablets: 500 mg	20–40	50 (max: 2 g) if <56 kg 3 g if 56–75 kg 4 g if >75 kg	Not recommended for young children 1.5 g if 40–55 kg 3 g if 56–75 kg 4 g if >75 kg	2 g
Rifampin ^c	Capsules: 150 mg, 300 mg Syrup: formulated in syrup from capsules	10–20	10–20	Not recommended for young children Adolescents: 10	Daily: 600 mg Twice weekly: 900 mg
Streptomycin	Vials: 1 g, 4 g	20–40	20–40		1 g

^aWhen isoniazid is used in combination with rifampin, the incidence of hepatotoxicity increases if the isoniazid dose exceeds 10 mg/kg/day.

^bMost experts advise against the use of isoniazid syrup because of instability and a high rate of gastrointestinal adverse reaction (diarrhea, cramps).

^cRifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (>50 kg body weight) daily doses of each drug.

TABLE 96.9 Treatment of Drug-Resistant Tuberculosis in Children^a

Drug	Dosage Forms	Daily Dosage (mg/kg/day)	Maximum Daily Dose
Amikacin	Vials: 500 mg, 1 g	15–30 (IM, IV)	1 g
Capreomycin	Vials: 1 g	15–30 (IM, IV)	1 g
Clofazimine	Capsules: 50 mg, 100 mg	50–100 mg/day	200 mg
Cycloserine	Capsules: 250 mg	10–20	1 g
Ethionamide	Tablets: 250 mg	15–20 given in 2 or 3 divided doses	1 g
Kanamycin	Vials: 75 mg/2 mL, 500 mg/2 mL, 1 g/3 mL	15–30 (IM, IV)	1 g
Levofloxacin	Tablets: 250 mg, 500 mg, 750 mg	Adults: 500–750 mg total/day Pediatric: 20–30 mg	1000 mg
Linezolid	Vials: 2 mg/mL Tablets: 600 mg Suspension: 20 mg/mL	10 (PO, IV)	600 mg
<i>p</i> -Aminosalicylic acid	Packets: 4 g	200–300 given in 2 to 4 divided doses	12 g

^aThere are no data to support intermittent dosing for second-line medications except for injectable agents.

IM, Intramuscularly; INH, isoniazid; IV, intravenously; PO, orally; PZA, pyrazinamide; RIF, rifampin; STM, streptomycin.

especially rifampin seems to increase the likelihood of hepatotoxicity.^{83,325} Monitoring of aspartate aminotransferase and alanine aminotransferase activity sometimes reveals transient increases during treatment with isoniazid in up to 40% of children,³³⁸ but the levels usually return spontaneously to normal without interruption of treatment.⁴⁷⁶ Liver enzyme abnormalities in adolescents receiving isoniazid are common occurrences and usually disappear spontaneously, but severe hepatitis can occur.^{362,391} The estimated incidence of hepatic failure in children on isoniazid monotherapy was 3.2 per 100,000,⁷¹⁶ jaundice was rare (0.06%), and transient elevations in hepatic transaminase levels were seen in 8%.¹⁵⁸ In children receiving isoniazid as part of multidrug therapy, rates of jaundice and elevated hepatic transaminase levels are higher, but still extremely low.¹⁵⁸

The possible occurrence of hepatitis raises the question of routine monitoring of liver enzyme levels once a month in all children receiving isoniazid. The advantage of doing so has to be weighed not only against the expense but particularly against the difficulty of ensuring regular monthly visits if the patient and parents know that every clinic visit entails a venipuncture. Most experts prefer to substitute routine questions about appetite and well-being, determination of weight, and a check of the appearance of the sclera and the size of the liver.^{72,487} Patients should be counseled to stop taking isoniazid and to contact the clinician immediately if significant nausea, vomiting, abdominal pain, or jaundice occurs during the use of isoniazid.

Allergic manifestations of isoniazid hypersensitivity are extraordinarily rare. Convulsions have been reported after doses of 100 mg/kg or more, as in suicide attempts.^{401,453,479,566} The treatment for isoniazid overdose is intravenous pyridoxine.

The usual dosage in children is 10 to 15 mg/kg/day, to a maximum of 300 mg/day. Isoniazid is available in tablets of 100 and 300 mg. A syrup of isoniazid in sorbitol (10 mg/mL) also is available; however, it is unstable at 37°C and should be kept cool. Significant gastrointestinal intolerance (nausea, diarrhea) develops in many children while they are taking the isoniazid suspension. If tablets are used, they are crushed easily in a dessert spoon, to which then is added in the same spoon a vehicle such as applesauce, mashed banana, or another palatable medium. The crushed tablets must never be added to the nursing bottle or offered in milk or water because they will be ingested only partially. If isoniazid is given concurrently with rifampin, the dose should not exceed 10 mg/kg/day.⁴⁵⁹ If the intramuscular form is used, for example, in a child with meningitis who is vomiting, the daily dose is the same as the daily oral dose but usually is divided and given every 8 to 12 hours. Isoniazid can interact with several other drugs, including acetaminophen, some antiepileptics (carbamazepine, phenytoin), and a few antituberculosis medications (INH increases the serum concentration of cycloserine and rifamycins and ethionamide can result in increased levels of INH). The dosage of each may need to be modified in a patient taking several drugs.²⁵

RIF is a semisynthetic drug derived from *Streptomyces mediterranei*. Active against a wide variety of both intracellular and extracellular organisms, it is bactericidal and more effective against mycobacteria than is any other drug except isoniazid. Most clinical isolates are susceptible to 5 µg/mL or less. The drug is absorbed readily from the gastrointestinal tract in the fasting state; peak serum levels of 6 to 10 µg/mL are achieved within 2 hours, and the drug is distributed widely in body fluids and tissues, including CSF. Excretion is mainly through the biliary tract; however, effective levels are achieved in the kidneys and urine. In many patients receiving treatment with rifampin, tears, saliva, urine, and stool turn orange as the result of a harmless metabolite, but patients and parents always must be warned in advance. Drawbacks include the relatively high cost; the rare occurrence of explosive hypersensitivity reactions with hemolytic anemia (associated with intermittent rifampin therapy²¹¹); and the occasional occurrence of leukopenia or thrombocytopenia.²²¹ Cholestatic hepatitis can be seen, and rifampin should be suspected as the culprit in children with transaminitis associated with elevated conjugated bilirubin. Rifampin has a number of drug interactions, including inactivation of oral contraceptives. It decreases levels of protease inhibitors, thus limiting its use in HIV-coinfected children on antiretroviral therapy. Rifabutin is preferred in this circumstance. Finally, there is a "therapeutic orphan" clause in the

United States for children younger than 5 years, which also means that no formulation is commercially available for young children. However, rifampin easily can be made into a suspension for use in children.

Rifampin should be used alone in treating tuberculosis infection with an isoniazid-resistant organism or for children who do not tolerate isoniazid. If isoniazid 20 mg/kg and RIF 15 to 20 mg/kg are used, the incidence of hepatotoxicity is appreciable. Therefore, when the two are used together, one would be wise to approximate the doses to isoniazid 10 mg/kg and RIF 15 to 20 mg/kg. Rifamate is a capsule containing both isoniazid (150 mg) and rifampin (300 mg). Two capsules supply the usual adult (more than 50 kg) daily dose of each drug. Rifamate may be appropriate for older children and adolescents.⁴ Rifater contains isoniazid, rifampin, and pyrazinamide together in one pill in varying concentrations. Rifapentine is a new rifamycin with a very long half-life, allowing for weekly administration. It is now recommended in combination therapy with isoniazid for the treatment of tuberculosis infection for persons 12 years of age or above.⁶²³ This regimen currently is recommended only under directly observed preventive therapy. Few pharmacokinetic data for rifapentine are available for young children. It appears that children require larger weight-normalized doses than adults.⁵² Long-term efficacy data for children and adolescents are scant.

Pyrazinamide contributes to the killing of *M. tuberculosis*, particularly at a low pH, such as within macrophages.⁵³⁰ The exact mechanism of action of this agent is a subject of controversy. Pyrazinamide has no effect on extracellular tubercle bacilli in vitro but clearly contributes to the killing of intracellular bacilli. Primary resistance is very rare, except that *Mycobacterium bovis* is intrinsically resistant. The drug diffuses readily into all areas, including CSF.^{157,185} The usual adult daily dose is 30 to 40 mg/kg. The adult dose is tolerated well by children, results in high CSF concentrations, and clearly is effective in therapy trials for tuberculosis in children.^{162,523,535,605} However, serum concentrations are lower in children than in adults taking a weight-equivalent dose.²¹⁸ Pyrazinamide appears to exert its maximal effect during the first 2 months of therapy. Hepatotoxicity can occur at high doses but rarely does at the usual dose. That said, pyrazinamide is the most common cause of drug-associated hepatitis in children receiving multidrug therapy for TB disease. Pyrazinamide routinely causes an increase in serum uric acid concentration by inhibiting its excretion through the kidneys. Toxic reactions in adults include flushing, cutaneous hypersensitivity, arthralgia, and overt gout; however, the considerable experience with this drug in children in Latin American countries, Hong Kong, and the United States has revealed few problems. It plays a major role in intensive, short-course treatment regimens.^{212,605} Use of pyrazinamide for the first 2 months allows therapy to be shortened from 9 to 6 months for most nonskeletal, nonmeningeal forms of tuberculosis. While pyrazinamide has few drug interactions, it can increase the levels of cyclosporine and rifamycins.

Ethambutol has been used for many years as a companion drug for isoniazid in adults. The usual oral dose is 20 mg/kg per day.¹⁶⁰ At this dose, the drug primarily is bacteriostatic, its major role being to prevent the emergence of resistance to other drugs. However, at doses of 25 mg/kg per day or 50 mg/kg given twice a week, ethambutol has some bactericidal action.^{123,203} Unfortunately, at these higher doses, optic neuritis or red-green color blindness has occurred in some adults. Regular visual field and color chart testing should detect these reversible effects early. The incidence of ophthalmologic toxicity in children is extremely low (0.05%), if it occurs at all, in part because children metabolize the drug faster than adults.¹⁶⁰ It is used frequently and safely in children, including in preverbal children in whom visual acuity evaluation is not possible, with life-threatening forms of tuberculosis or who are at risk for drug-resistant tuberculosis. However, it diffuses poorly into CSF.¹⁵⁷ In the United States, it is used with isoniazid, rifampin, and pyrazinamide as first-line therapy for children with suspected tuberculosis when drug-susceptibility results are not yet known. Ethambutol has few drug interactions.

Ethionamide is an effective and well-tolerated drug in children at a dose of 15 to 20 mg/kg/day divided into two or three doses given after meals. Children rarely complain about its sulfurous taste, which is repulsive to adults. Related to isoniazid, it likewise diffuses readily into CSF.^{161,163,261} Ethionamide is used in cases of drug-resistant tuberculosis and tuberculous meningitis, where it can replace ethambutol

in the regimen. Unfortunately, no convenient pediatric dosage form is available. Use of ethionamide may be limited by its most common side effect—vomiting. Ethionamide can increase serum concentrations of isoniazid and cycloserine. Ethionamide resistance is common in children with isoniazid resistance.⁵⁴⁶

Second-line medications are used when patients have drug-resistant strains of *M. tuberculosis* or when they are intolerant of first-line medications. Second-line medications are notable for more frequent or severe adverse effects, fewer pediatric pharmacokinetic data, and fewer available child-friendly formulations than first-line drugs. Drug susceptibility testing for some second-line agents (cycloserine, linezolid, clofazimine) is less well validated than for first-line medications, and correlation between in vitro susceptibility and clinical response is less evident.

Streptomycin is used in conjunction with isoniazid and rifampin in life-threatening forms of tuberculosis. It is bactericidal and tolerated well in children in the usual dose of 20 to 40 mg/kg/day intramuscularly up to 1 g. Usually, streptomycin can be discontinued within 1 to 3 months if clinical improvement is definite, whereas the other two or three drugs are continued by mouth. Use of streptomycin and other injectable drugs (amikacin, capreomycin, kanamycin) is limited by the dose-dependent incidence of ototoxicity and nephrotoxicity. An isolate may be resistant to some injectable agents and remain susceptible to others. Streptomycin is rarely used in the United States, where less toxic alternative injectables are available.

p-Aminosalicylic acid formerly was part of the standard treatment of tuberculosis. However, it is a purely bacteriostatic drug that has been superseded by more powerful drugs (e.g., rifampin, pyrazinamide). It is used only for the treatment of drug-resistant tuberculosis. Cycloserine, linezolid, and clofazimine are other drugs sometimes used in patients with MDR-TB.⁵⁵⁸ Cycloserine diffuses well into tissues and CSF,¹⁵⁷ but its use may be limited by neuropsychiatric side effects (including depression, suicidality, psychosis, aggression, tremors, paresthesias),⁶⁵⁵ which are more common in adults. Toxicity is more common when serum levels exceed 30 µg/mL. Linezolid demonstrates modest early bactericidal activity but little extended early bactericidal activity¹⁵¹; its use may be limited by optic neuritis, peripheral neuropathy, and bone marrow suppression. Despite these adverse effects, it has been widely used in the treatment of patients with MDR-TB and XDR-TB. Almost 90% of adults experience sputum conversion after receipt of linezolid-containing regimens.⁷²⁵ There are few published data regarding linezolid use in children with drug-resistant tuberculosis. Clofazimine has antiinflammatory properties, and there is little documented resistance. Addition of clofazimine to an optimized background regimen resulted in more rapid cavity closure and sputum culture conversion, as well as increased cure in a cohort of patients with MDR-TB in China.⁶⁴¹ Clofazimine's use may be limited by pink or brownish-black skin pigment changes.¹¹⁰

Several of the fluoroquinolones, especially levofloxacin and moxifloxacin, have significant antituberculosis activity,^{303,420} but they are not used routinely in children with drug-susceptible tuberculosis because of the possible destruction of growing cartilage seen in animal models. However, the dire consequences of drug-resistant tuberculosis lead many experts to use them successfully and with little apparent toxicity in children with MDR-TB disease.⁵⁵⁹ These drugs are bactericidal and diffuse into tissues and CSF well.¹⁵⁷ Children require higher milligram per kilogram dosing to achieve the same serum levels observed in adults.²⁰⁵ If an isolate is resistant to one fluoroquinolone, resistance to other fluoroquinolones is common.

Microbiologic Basis for Treatment

Laboratory observations of *M. tuberculosis* and the results of clinical therapy trials have led to a hypothesis concerning the actions of various drugs and drug combinations.^{176,221,417,418} The tubercle bacillus can be killed only during replication, which occurs in organisms that are active metabolically. In one model, bacilli in a host exist in different populations. They are active metabolically and replicate freely where oxygen tension is high and the pH is neutral or alkaline. Environmental conditions for growth are best within cavities, and such conditions can lead to a large bacterial population. Adults with reactivation-type pulmonary tuberculosis usually have all three populations of tubercle bacilli. Children

with pulmonary tuberculosis, and patients of all ages with only extrapulmonary tuberculosis, are infected with a much smaller number of tubercle bacilli because the cavitory population is not present.

Naturally occurring drug-resistant mutant organisms occur within large populations of tubercle bacilli even before chemotherapy is started. All known genetic loci for drug resistance in *M. tuberculosis* are located on the chromosome; no plasmid-mediated resistance is known. The rate of resistance within populations of organisms is related to the rate of mutations at these loci.^{407,638,646,724,726} Although a large population of bacilli as a whole may be considered drug susceptible, a subpopulation of drug-resistant organisms occurs at a fairly predictable rate. The mean frequency of these drug-resistant mutants is about 10^{-6} but varies among drugs: streptomycin, 10^{-5} ; isoniazid, 10^{-6} ; and rifampin, 10^{-7} .¹³⁸ A cavity containing 10^9 tubercle bacilli has thousands of single drug-resistant mutant organisms, whereas a closed caseous lesion contains few if any resistant mutants.

The two microbiologic properties of population size and drug resistance mutation explain why single antituberculosis drugs cannot cure cavitory tuberculosis. In the mid 1940s, streptomycin alone was given to adults with cavitory pulmonary tuberculosis.⁴⁰² Within 3 months, 80% of patients had significant numbers of streptomycin-resistant organisms. This phenomenon has been observed for every antituberculosis drug developed subsequently. However, the natural occurrence of resistance to one drug is independent of resistance to any other drug because the resistance loci are not linked. The chance of having even one organism “naturally” resistant to two drugs is on the order of 10^{-11} to 10^{-13} . Populations of this size in patients are extremely rare, and mutants naturally resistant to two drugs are nonexistent.

The population size of tubercle bacilli within a patient determines the appropriate therapy. For patients with large bacterial populations (tuberculosis disease), many single drug-resistant mutants are present and at least two antituberculosis drugs must be used.¹⁴⁰ Conversely, for patients with tuberculosis infection but no disease, the bacterial population is small (10^3 to 10^4 organisms), drug-resistant mutants are rare findings, and a single drug can be used.

Some antituberculosis drugs, such as isoniazid, rifampin, streptomycin, and fluoroquinolones, are bactericidal against *M. tuberculosis*. Other drugs, including ethionamide, *p*-aminosalicylic acid, and low-dose ethambutol, are bacteriostatic. The earliest treatment regimens for tuberculosis combined the killing action of a bactericidal drug with a bacteriostatic drug that would suppress replication of drug-resistant mutant organisms. A small number of organisms survived despite administration of chemotherapy, and 18 to 24 months of treatment was necessary to permit host defenses to eliminate persisting organisms. Despite the prolonged treatment period, relapse rates were 5% to 15%, mostly a result of poor adherence.

The availability of rifampin and the rediscovery of pyrazinamide in the early 1970s effected radical change in antituberculosis chemotherapy. These two drugs have the most potent sterilizing action, the ability to kill tubercle bacilli within lesions as quickly as possible. The addition of rifampin to isoniazid for the treatment of pulmonary tuberculosis leads to cure rates approaching 100% with only 9 months of treatment. The further addition of pyrazinamide shortens the necessary treatment duration to only 6 months.

In the international community, there has been a shift away from intermittent therapy, driven in part by concern about intermittent rifampin use in HIV-infected adults selecting for rifampin-resistant isolates. However, there is a wealth of operational experience with intermittent therapy in the United States for both adults and children. Duration of therapy may need to be extended in HIV-infected patients. One metaanalysis found that relapse and failure rates were higher in thrice-weekly compared with daily therapy and there was a trend toward higher relapse rates in patients who were treated for 6 months when compared with those treated for at least 8 months.³⁰⁶

Treatment of the Stages of Tuberculosis

Exposure

Children exposed to potentially infectious adults with pulmonary tuberculosis should begin treatment, usually with isoniazid only, if the child is younger than 5 years or has other risk factors for the rapid

development of tuberculosis disease, such as immunocompromise.^{629,711} Failure to do so may result in the development of severe tuberculosis disease even before the tuberculin skin test becomes reactive; the “incubation period” of disease may be shorter than that for the skin test. The child is treated for a minimum of 2 months after contact with the infectious case is broken (by physical separation or by effective treatment of the case). After 2 months, the tuberculin skin test is repeated. If the second test result is positive, infection is documented and isoniazid should be continued for a total duration of 9 months; if the second skin test result is negative, treatment can be discontinued. If the exposure was to a person with an isoniazid-resistant but rifampin-susceptible isolate, then rifampin is the recommended treatment for 4 months.

Two special circumstances of exposure deserve attention. A difficult situation arises when exposed children are anergic because of HIV infection. These children are particularly vulnerable to rapid progression of tuberculosis, and it will not be possible to determine whether infection has occurred. In general, these children should be treated as though they have tuberculosis infection.

The second situation is potential exposure of a neonate to a mother (or other adult) with a positive tuberculin skin test result or, rarely, a nursery worker with contagious tuberculosis.^{346,620} Management is based on further evaluation of the mother:

1. *The mother has a normal chest radiograph:* no separation of the infant and mother is required. Although the mother should receive treatment for tuberculosis infection and other household members should be evaluated for tuberculosis infection or disease, the infant needs no further workup and no treatment is needed unless a case of disease is found.
2. *The mother has an abnormal chest radiograph:* the mother and child should be separated until the mother has been evaluated thoroughly. If the radiograph, history, physical examination, and analysis of sputum reveal no evidence of pulmonary tuberculosis in the mother, a reasonable assumption is that the infant is at low risk for acquiring infection. The radiographic abnormality is due to another cause or a quiescent focus of previous tuberculosis infection. However, if the mother remains untreated, contagious tuberculosis may develop later and the infant will be exposed. Both the mother and infant should receive appropriate follow-up care, but the infant does not need treatment. If the radiograph and clinical history are suggestive of pulmonary tuberculosis, the child and mother should remain separated until both have begun appropriate chemotherapy. The infant should be evaluated for congenital tuberculosis. The placenta should be examined. If the mother has no risk factors for drug-resistant tuberculosis, the infant should receive isoniazid and close follow-up care. The infant should have a tuberculin skin test at 3 or 4 months after the mother is judged to be contagious no longer; evaluation of the infant at this time follows the guidelines for other exposure of children. If the mother has tuberculosis caused by a multidrug-resistant isolate of *M. tuberculosis* or she has poor adherence to therapy, the child should remain separated from her until she is no longer contagious or the infant can be given BCG vaccine and be kept separated until the vaccine “takes” (marked by a reactive tuberculin skin test).

Infection

The recommendation for treatment of asymptomatic tuberculin-positive individuals is based on data from several well-controlled studies; it applies particularly to children and adolescents who are at high risk for the development of overt disease but at very low risk for development of the main toxic manifestation of isoniazid therapy, which is hepatitis.^{165,195,446,459,593} The large, carefully controlled US Public Health Study of 1955, followed by others both in this country and abroad, demonstrated the favorable effect of 12 months of isoniazid on the incidence of complications as a result of both lymphohematogenous and pulmonary spread.²⁵⁹ The younger the infected person, the greater the benefit.¹²⁰

The American Thoracic Society and the CDC¹³ recommend that isoniazid for treatment of tuberculosis infection be given to several high-risk groups (Box 96.2). The question arises regarding how long the protective effect can be expected to last. Comstock and associates,¹¹⁸ in their final report on isoniazid prophylaxis in Alaska, demonstrated

BOX 96.2 Persons in Whom Isoniazid (or Other Regimens) Should Be Initiated to Prevent Progression to Tuberculosis

Household members and other close associates of potentially infectious tuberculosis cases

All contacts of any age with a Mantoux tuberculin skin test reading of 5 mm or greater and without a documented history of reaction in the past or with a positive interferon gamma release assay (IGRA) should be considered recently infected and receive therapy if they have not been previously treated

Newly infected people, regardless of age, who have had a tuberculin skin test or IGRA conversion within the past 2 years

People with HIV infection who have a reaction of 5 mm or greater to a Mantoux test

People of any age with tuberculosis infection in the past who received inadequate treatment

People of any age with a positive tuberculin skin test or positive IGRA and an abnormal but stable chest radiograph

People with significant tuberculin reactions or positive IGRAs who have special clinical situations, including silicosis, diabetes mellitus, prolonged corticosteroid therapy, immunosuppressive therapy, hematologic malignant disease, and end-stage renal disease

All children and adolescents with a “positive” tuberculin skin test reaction or interferon release assay result

the protective effect of 1 year of chemoprophylaxis to be at least 19 years. Hsu²⁵⁷ described 2494 patients monitored for up to 30 years and showed that adequate drug prophylaxis prevented reactivation of tuberculosis infection during adolescence and into young adulthood. It seems reasonable to hope that the decreased risk for active tuberculosis after isoniazid prophylaxis may, in fact, be lifelong in individuals infected with isoniazid-susceptible tubercle bacilli. Optimal treatment of infection caused by isoniazid-resistant *M. tuberculosis* is unclear. Rifampin alone is recommended and widely used, although failures have been reported.³⁶⁰

The duration of isoniazid treatment initially was set arbitrarily at 12 months.²⁷² A large trial comparing regimens of daily isoniazid for 12, 24, and 52 weeks with placebo for their ability to prevent tuberculosis disease was conducted in eastern Europe with adults who had old fibrotic lesions caused by tuberculosis. Therapy for 1 year was most effective, especially if the patients were adherent to it. However, therapy for 24 weeks afforded a fairly high level of protection. A subsequent analysis concluded that the 24-week duration of preventive therapy was more cost effective for adults than was the 52-week duration.⁵⁹² Subsequently, many health departments have accepted 6 months of isoniazid preventive therapy as their standard regimen for adults. However, the cost-effectiveness analysis does not apply to children. A recent review of all published studies concluded that the effectiveness of isoniazid therapy increased up to 9 months’ duration, but no additional benefit was achieved with a longer duration.¹³

AAP and CDC recommend three regimens¹³ for tuberculosis infection: 9 months of isoniazid; 4 months of rifampin; and 12 once-weekly doses of isoniazid and rifapentine. These three and other regimens used for TB infection therapy caused by presumably susceptible strains are described in Table 96.10.¹²⁴ While 9 months of isoniazid is very efficacious, adherence is abysmal, with approximately 50% of children completing therapy.¹²⁸ A shorter duration of effective treatment for tuberculosis infection is highly desirable to improve compliance and effectiveness.³⁸⁶ Short-course regimens (3–4 months) with isoniazid and rifampin have been used frequently in the United Kingdom,^{188,602} but are not yet recommended in the United States. Four months of rifampin is the shortest regimen recommended for daily administration in the United States. In one study, children receiving rifampin were over 7 times more likely to complete therapy than children receiving 9 months of isoniazid.¹²⁹

More recently, pediatric data (children ≥2 years) were published for 12 weekly doses of isoniazid combined with a long-acting rifamycin,

TABLE 96.10 Available Regimens for the Treatment of Tuberculosis Infection

Regimen	Formulations	Dose (mg/kg) [Maximum Dose (mg)]	Advantages/Disadvantages	Selection Scenario(s)
INH + RPT × 12 doses (3HP)	INH: as above Rifapentine: Tablets: 150 mg	INH: 15 (round to nearest 50 mg or 100 mg) [900] RIF ^c : 10–14 kg: 300 mg 14.1–25 kg: 450 mg 25.1–32 kg: 600 mg 32.1–49.9 kg: 750 mg ≥50 kg: 900 mg	Pro: adherence Con: availability; need for administration via DOT	Short-course therapy desirable; need to complete therapy urgently (e.g., because child will be traveling or completion is necessary before child is to receive immunosuppressive therapy)
RIF × 4 mo	Capsule: 150 mg, 300 mg	10–20 [600]	Pro: adherence; availability Con: cost; potential drug interactions	Short-course therapy is desirable and not a candidate for 3HP (e.g., age <2 y); infected child had contact with adult with INH-resistant TB
INH × 9 mo (CDC)	Tablets: 100, 300 mg Suspension: 10 mg/mL ^a	Daily: 10–15 [300] Biweekly ^b : 20–30 [900]	Pro: ~20% added benefit over INH × 6 mo; low cost Con: low (<50%) adherence	Medication interactions preclude use of RIF; intolerant of RIF; cannot afford RIF and not eligible to receive medication via local health department; infected child had contact with adult with RIF-resistant, INH-susceptible TB
INH × 6 mo (WHO)	As above	Daily: 10–15 [300] Biweekly ^b : 20–30 [900]	Pro: adherence >9 mo Con: slightly reduced benefit compared with 9-mo regimen (assuming both taken as indicated)	
INH + RIF × 3 mo (BTS)	As above	INH: 10–15 [300] RIF: 10–15 [600]	Pro: adherence Con: slightly increased risk of side effects compared to monotherapy	Short-course therapy desirable and 3HP unavailable or family reluctant to receive medication under DOT Use of this regimen likely to be low in the US given availability of 3HP
RIF + PZA × 2 mo	RIF: as above PZA: Tablets: 500 mg	Study in adults: RIF: 600 mg PZA: 15–20 mg/kg/day [2 g]	Pro: adherence Con: hepatotoxicity; now only recommended for patients initially suspected of having TB disease	Children initially started on therapy for TB disease and later suspected of having TB infection instead; if at least 2 mo of RIF/PZA have been completed, this comprises adequate TB infection therapy

^aMany commercially available formulations of INH suspension are sorbitol based and cause profuse diarrhea; providers should limit use of INH suspension only to very young infants. INH tablets can be crushed and mixed with pureed food or a small volume of formula even for young babies.

^bIntermittent dosing should only be used if the child is receiving DOT.

^cRifapentine dose is in mg, not mg/kg.

BTS, British Thoracic Society; CDC, Centers for Disease Control and Prevention; DOT, directly observed therapy; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine; TB, tuberculosis; WHO, World Health Organization.

rifapentine (termed 3HP).^{623,683} This regimen was as safe and at least as effective in preventing disease as 9 months of isoniazid, but had far higher completion rates. Use of this regimen has been limited by drug availability and by the need to administer medications under directly observed therapy. While in adults, influenza-like illness, myalgias (which peak in the second or third week of therapy and are responsive to nonsteroidal antiinflammatory drugs), and skin rashes are common,⁶²² these seem to be infrequently observed in children.

Isoniazid preventive therapy in HIV-infected patients has been best studied in adults.³⁹⁴ The theoretical advantages of this therapy in settings with high tuberculosis prevalence are that persons may be exposed without knowledge of a specific source case; HIV-infected patients may be anergic to the tuberculin skin test (and have high rates of indeterminate IGRA results); and HIV-infected persons with tuberculosis infection are at high risk for rapidly progressing to tuberculosis disease. The potential disadvantages are the potential of selecting for isoniazid-resistant isolates, inadvertently treating patients for infection when they have disease, drug toxicity in a patient who may not have infection, and cost. Randomized trials have shown IPT to be effective in preventing tuberculosis disease-free survival in adults, irrespective of the use of HAART. Isoniazid preventive therapy in HIV-infected children is controversial. Two large randomized studies have evaluated its impact on survival and tuberculosis disease-free survival in HIV-infected African children. Whereas one study showed decreased all-cause mortality and decreased cases of tuberculosis disease,⁷²¹ a second study found no benefit.³⁷⁰ Additional data are needed to determine what role isoniazid preventive

therapy should have in national tuberculosis programs in settings with high prevalence of both HIV and tuberculosis.

Chemotherapy for Children

Clinical trials of antituberculosis drugs in children are difficult to perform, mostly because of the difficulty in obtaining positive cultures at diagnosis or relapse and the need for long-term follow-up.^{605,606} Historically, recommendations for treating children with tuberculosis have been extrapolated from clinical trials of adults with pulmonary tuberculosis.⁵⁸⁵ However, during the past 2 decades, a large number of clinical trials involving only children have been reported. In 1983, Abernathy and colleagues² reported successful treatment of 50 children with tuberculosis in Arkansas using isoniazid and rifampin daily for 1 month, then twice weekly for 8 months. The success rate virtually was 100%. Most pulmonary infiltrates cleared by the end of therapy, but hilar adenopathy usually was still present radiographically and then gradually cleared over 2 to 3 years. Patients with only hilar adenopathy can be treated successfully with isoniazid and rifampin for 6 months.^{277,511} In children with cavitary lung disease or children with persistently positive sputum cultures after 2 months of effective therapy, therapy may be extended to 9 months to decrease relapse rates.⁹⁴

Several major studies of 6-month therapy in children with at least three drugs in the initial phase have been reported.^{8,47,266,321,636,642,662} The regimen used most commonly was 6 months of isoniazid and rifampin supplemented during the first 2 months with pyrazinamide. The overall success rate was greater than 98% and the incidence of clinically

significant adverse reactions less than 2%. Use of streptomycin did not improve treatment outcomes. Use of twice-weekly medications (under directly observed therapy) during the continuation phase was as effective and safe as was daily administration. Three studies used twice-weekly therapy throughout the treatment regimen with excellent success.^{321,642,678} The 6-month, three-drug regimen is successful, tolerated well, and less expensive.^{627,663} It also effects a cure faster, so the likelihood of successful treatment is greater if the child becomes nonadherent later in therapy. Current CDC and ATS recommendations are to include ethambutol with isoniazid, rifampin, and pyrazinamide during the initial phase unless the child's source case is known to have an *M. tuberculosis* isolate susceptible to first-line medications.

The optimal duration of therapy and dosing interval for antituberculous medications in children coinfecting with HIV is unclear. Relapse or failure in up to 12% of HIV-infected children treated for 6 months has been reported.³⁴⁵ The optimal timing for initiation of HAART in children with tuberculosis disease is unclear, but extrapolation from adult data suggests a survival benefit from initiation within 2 to 8 weeks.^{291,568} Selection of a HAART regimen may be complicated by the known interaction of rifampin with protease inhibitors. Although these interactions are decreased by using rifabutin, some nations have deferred protease inhibitors to second-line HAART because of these interactions. Further complicating care of the coinfecting child is the risk for IRIS and that children on both HAART and antituberculous medications tend to tolerate both classes of medication more poorly than children receiving one or the other.⁶⁸⁰

Extrapulmonary Tuberculosis

Controlled treatment trials for various forms of extrapulmonary tuberculosis are rare. In most reports, extrapulmonary cases have been combined with pulmonary cases and often are not analyzed separately. Several of the 6-month, three-drug trials in children included extrapulmonary cases.^{47,321} Most non-life-threatening forms of extrapulmonary tuberculosis respond well to a 9-month course of isoniazid and rifampin^{175,177} or to a 6-month regimen including isoniazid, rifampin, and pyrazinamide.²⁷³ One exception may be bone and joint tuberculosis, which may have a high failure rate when 6-month chemotherapy is used, especially if surgical intervention has not occurred.¹⁷⁵ Tuberculous meningitis usually is not included in trials of extrapulmonary tuberculosis therapy because of its serious nature and low incidence. Treatment with isoniazid and rifampin for 9 to 12 months generally is effective.⁶⁸⁴ Data from Thailand showed that a 6-month regimen that included pyrazinamide for serious tuberculous meningitis led to fewer deaths and better outcomes than did longer regimens that did not contain pyrazinamide.²⁷⁸ Most children are treated initially with four drugs (isoniazid, rifampin, pyrazinamide, and ethionamide or an injectable agent). Ethambutol crosses the blood-brain barrier very poorly,¹⁵⁷ making it a suboptimal choice for treating children with tuberculous meningitis. Treatment with pyrazinamide and the fourth drug is stopped after 2 months, and isoniazid and rifampin are continued for a total of 9 to 12 months.¹⁶¹

Drug-Resistant Tuberculosis in Children

The incidence of drug-resistant tuberculosis is increasing because of poor adherence by the patient, the availability of some antituberculous drugs in noncontrolled over-the-counter formulations, and poor management by physicians.^{49,199,200,372,455} In the United States, approximately 13% of *M. tuberculosis* isolates are resistant to at least one drug and 1.2% are MDR-TB¹¹²; rates of drug resistance are more than twice as high in foreign-born cases than in US-born persons with disease. Initial drug resistance rates of up to 80% have been noted in adults with pulmonary tuberculosis in some countries,³⁷³ and rates of 20% to 30% are common findings. Resistance is most common to streptomycin and isoniazid and still is relatively rare to rifampin.^{144,251,419,729} Rifampin monoresistance is unusual¹⁶⁶; in the vast majority of cases, rifampin resistance is seen in conjunction with isoniazid resistance. Certain epidemiologic factors—disease in an Asian or Hispanic immigrant to the United States, homelessness in some communities, and history of previous antituberculous therapy—correlate with drug resistance in adult patients.¹⁶ Patterns of drug resistance in children tend to mirror those found in adult patients in the population.^{86,543,565,619} Outbreaks of drug-resistant tuberculosis in

children occurring at schools have been reported.^{86,516} Individual cases also have been recognized. The key to determining drug resistance in childhood tuberculosis usually comes from the drug susceptibility results of the infectious adult contact case's isolate.

Therapy for drug-resistant tuberculosis is successful only when at least two bactericidal drugs are given to which the infecting strain of *M. tuberculosis* is susceptible.^{74,480,542,647} If only one effective drug is given, secondary resistance will develop. Exact treatment regimens must be tailored to the specific pattern of drug resistance. The duration of therapy usually is extended to at least 9 to 12 months if either isoniazid or rifampin can be used and to at least 18 to 24 months if resistance to both drugs is present.²⁷⁴ Children tend to tolerate second-line antituberculous drugs well, and community-based treatment usually is successful.^{170,432} This is reflected in the lower mortality rates seen in children than in adults with MDR-TB. One pediatric series of children with MDR-TB in South Africa demonstrated 25-fold and almost 40-fold increases in mortality for children with MDR-TB and HIV coinfection and extrapulmonary tuberculosis, respectively.⁵⁵⁹ On occasion, surgical resection of a diseased lung or lobe is required.^{276,717} One metaanalysis showed that estimated success rates for pulmonary resection in adults with MDR-TB were over 80%,⁷¹⁶ a substantial improvement over the 50% to 65% survival seen with medical therapy alone.⁴⁶⁶

Treatment of a child with MDR-TB or XDR-TB exposure or infection is controversial. The benefit of preventing progression to disease, especially in a child with ongoing exposure, must be balanced against the scant pharmacokinetic, safety, and efficacy data available for many second-line medications. The role of treating the exposed child with contact to an adult with MDR-TB is unclear. For infected children whose source case has MDR-TB, combination therapy with one or two drugs to which the isolate is susceptible may be considered; use of a 12-month course of fluoroquinolones in the regimen (either as monotherapy or as part of combination therapy) has been effective,^{28,395} although longitudinal outcomes are unknown. Many children require treatment modification due to adverse events if more than one drug is given. Optimal treatment duration is unknown. At least 6 to 9 months of therapy should be attempted. An expert in tuberculosis always should be involved in the management of children with drug-resistant tuberculosis infection or disease.

Adherence and Directly Observed Therapy

Nonadherence with drug treatment by patients is a major problem in control of tuberculosis because of the long-term nature of its treatment.^{410,632,675} As treatment regimens become shorter in duration, adherence assumes an even greater importance. Suspected cases of tuberculosis must be reported to the local health department so that it can perform the necessary contact investigations and assist both patients and health care providers in overcoming barriers to adherence. To comply, the patient and family must know what is expected of them through verbal and written instructions in the patient's preferred language. Missed appointments should be brought quickly to the attention of the responsible public health officials, who may be able to use incentives or enablers, behavior modification, or, rarely, confinement to ensure adherence. The success of twice-weekly therapy, especially after a period of daily administration of medications, allows directly observed therapy to be given by a health care professional in cases of proven or suspected nonadherence.^{102,103,275,651} Most experts hold that twice-weekly medication should be administered only under the direct observation of a health care worker.^{317,698} Direct observation means that a health care worker or other nonrelated third party (e.g., teacher, school nurse, social worker) is physically present while the patient ingests the medication. A substantial number of children and their families are nonadherent with therapy. One study of isoniazid preventive therapy after tuberculosis exposure showed that 33% took medications for at least 4 months and only 12% completed a 6-month course.²⁰⁷ Adherence is inaccurately predicted by physicians. There are no documented differences in completion rates by child's age or duration of time the family has been in the United States.⁴⁹⁸ In one study, the only factor associated with completion of tuberculosis infection therapy was health department-enabled medication administration.¹²⁸ In most communities in the United States and in an increasing number of other nations, directly observed therapy is the

standard of care for all patients with tuberculosis disease.^{90,189} However, when directly observed therapy cannot be used, structured behavior interactions can increase compliance with treatment.^{82,642}

Summary of Treatment Recommendations

1. A regimen of isoniazid and rifampin for 6 months, supplemented with pyrazinamide during the first 2 months and ethambutol for 2 months or until the source case is known to be susceptible to all first-line agents, is standard therapy for children with suspected intrathoracic tuberculosis in the United States and Canada.
2. An alternative regimen is isoniazid and rifampin for 9 months. The disadvantages of this regimen include a longer duration, the potential for increased drug resistance during therapy, and less effectiveness if the patient absconds from treatment. This regimen should be used only if pyrazinamide cannot be tolerated.
3. After an initial 2 weeks to 2 months of daily drug administration, drugs can be given twice weekly under directly observed therapy with excellent effectiveness.⁴⁹⁴ With patients for whom social or other restraints prevent reliable daily self-administration even during the initial phase of therapy, drugs can be given two or three times per week from the beginning under directly observed therapy.
4. In most cases, extrapulmonary tuberculosis can be treated with the same regimens as used for pulmonary tuberculosis, although data for tuberculous meningitis and bone or joint disease are relatively lacking. The duration of therapy is extended for tuberculous meningitis, osteoarticular tuberculosis, and children with substantial pulmonary disease after 6 months of therapy.^{94,712}
5. Optimal therapy for tuberculosis in children with HIV infection has not been established.⁶²⁸ Most HIV-infected adults with tuberculosis respond well to antituberculosis drugs but may require longer durations of treatment; higher failure and relapse rates were noted if rifamycins were used for only 6 months.³⁰⁶ Immunosuppressed children with tuberculosis, including those with HIV infection, should be treated with at least three drugs initially, and treatment should be continued for a minimum of 9 months. Intermittent therapy is not recommended for HIV-infected children.⁷¹² HIV testing is recommended for all infants and children with tuberculosis disease.
6. Tuberculosis disease occurring during pregnancy should be treated with a 9-month regimen of isoniazid and rifampin, supplemented during the initial phase with ethambutol (streptomycin should not be used). The use of pyrazinamide in pregnant patients is controversial although probably safe.

Corticosteroids

Corticosteroids have a place in the treatment of patients with tuberculosis. They should never be used except under cover of effective antituberculosis drugs. Corticosteroids would be expected to be beneficial in situations in which the host inflammatory reaction is contributing to tissue damage or is impairing function.

Corticosteroids often are a useful addition to antituberculosis drugs if suppression of inflammatory reaction is desired, such as in the following situations⁵⁸⁴:

1. In patients with tuberculous meningitis in whom increased intracranial pressure is present.⁶⁵⁷ The major actions are to reduce vasculitis, inflammation, and, ultimately, intracranial pressure. Not only is reduction of pressure desirable, but lowering of the pressure also probably favors the circulation of chemotherapeutic drugs through the brain and meninges.¹⁹³ One metaanalysis demonstrated lower rates of mortality and long-term neurologic sequelae in patients with tuberculous meningitis treated with corticosteroids than in children and adults not treated with corticosteroids.⁴⁹⁹
2. In patients with acute pericardial effusion in whom tamponade is occurring. Relief of symptoms takes place within hours. Use of corticosteroids reduced symptoms and mortality but not echocardiographic resolution of the effusion in both HIV-infected²²⁸ and HIV-uninfected⁶³⁰ children and adults. There appears to be a reluctance to use corticosteroids in HIV-infected patients with tuberculous pericarditis,⁷⁰⁸ but increased mortality has not occurred when corticosteroids are utilized in conjunction with antituberculosis chemotherapy.

3. In patients with pleural effusion associated with mediastinal shift and impending respiratory failure.³³⁷ The long-term course probably is the same with or without corticosteroids, but symptomatic improvement usually is dramatic. One randomized trial of corticosteroid use for pleural tuberculosis in HIV-infected adults showed more rapid disease resolution, but increased rates of Kaposi sarcoma and no change in mortality, in corticosteroid recipients¹⁸⁶; although both groups had similar CD4 cell counts and viral loads, no anti-retroviral agents were provided, making it difficult to extrapolate the findings. Similar data are unavailable for children.
4. In patients with miliary tuberculosis if the inflammatory reaction is so severe that it produces alveolocapillary block with cyanosis.
5. In patients with enlarged mediastinal lymph nodes that are causing respiratory difficulty or a severe collapse-consolidation lesion, particularly in the middle or lower lobes, when bronchiectasis is likely to be a troublesome sequela.⁴⁴⁴ Under either of these circumstances, a course of corticosteroids is warranted, with the realization that it will be more successful in an early infection because inflammation characterizes the first stages of tuberculosis. If caseation already is advanced, corticosteroids will be of little benefit.
6. In patients with IRIS whose reactions are either severe (e.g., airway compromise, brainstem herniation) or whose symptoms are refractory to therapy with nonsteroidal antiinflammatory medications.⁴⁰⁸

The dosage of corticosteroids should be in the antiinflammatory range, that is, prednisone 1 to 2 mg/kg per day for 4 to 6 weeks with gradual withdrawal. Some experts prefer dexamethasone, but no comparative trials have been published.

Activity

Activity need not be restricted in children with tuberculosis, except when a particular complication is inevitable (shortness of breath in pleural effusion, immobilization for a vertebral lesion).

Isolation

Isolation should be maintained for children with cavitary lesions, productive cough with acid-fast stain-positive sputum, draining sinuses, or renal tuberculosis until their secretions are negative on smear and preferably on culture. Young children are virtually noninfectious because they rarely cough and because their bronchial secretions contain few bacilli compared with those of adults with tuberculosis. Guidelines issued by the CDC state that most children with typical tuberculosis do not require isolation in the hospital.⁹⁵ Children with possible pulmonary tuberculosis should be treated as potentially infectious if they have a cavity or extensive upper lobe infiltrate, if they have a productive cough (especially if the sputum is acid-fast smear positive), or during high-risk procedures such as bronchoscopy. Although most children are not contagious with tuberculosis, the same cannot be said of their adult caregivers. Two studies in a relatively high-prevalence area of the United States showed that up to 17% of children admitted to the hospital for tuberculosis were accompanied by an adult with as yet undiagnosed tuberculosis.^{126,436} Consideration should be given to screening caregivers of these children symptomatically or radiographically.

Follow-Up

Follow-up of children treated with antituberculosis drugs has become somewhat more streamlined in recent years. While receiving chemotherapy, the patient should be seen monthly, both to encourage regular intake of the prescribed drugs and to check, by a few simple questions (concerning appetite, well-being) and a few observations (weight gain; appearance of the skin and sclerae; palpation of the liver, spleen, and lymph nodes), that the disease is not spreading, and that toxic effects of the drugs are not appearing.⁷⁰⁰ Repeated chest radiographs should be obtained 1 to 2 months after the onset of chemotherapy to ascertain the maximal extent of disease before chemotherapy takes effect; thereafter, radiographs rarely are necessary.³¹³ Radiographic worsening at this time may be an indication of IRIS, the presence of drug-resistant tuberculosis, and/or adherence difficulties. Therefore, it is important to obtain this radiograph before stopping four-drug therapy and starting isoniazid and rifampin. If the radiograph at 1 to 2 months has normalized, subsequent imaging is unnecessary unless the child's disease worsens clinically. If the radiograph

at 1 to 2 months is abnormal, repeating imaging at the conclusion of therapy is helpful to reestablish a new radiographic baseline for the child. Chemotherapy has been so successful that follow-up beyond its termination is not necessary, except for children with serious disease, such as tuberculous meningitis, or those with extensive residual chest radiographic findings at the end of chemotherapy.

Case Reporting

Every case of definite or suspected tuberculosis, by United States law,⁸⁹ must be reported immediately by telephone to the health authority²¹³ to ensure prompt contact investigation.²⁵⁵ Free antituberculosis drugs are available for diagnosed cases and for close contacts in almost every state of the United States and in many countries.

Prevention

Prevention of tuberculosis can be subdivided logically to consider the following circumstances:

- 1. Protection against exposure to the disease
- 2. Use of antituberculosis drugs in tuberculin-negative individuals at high risk for development of infection⁵⁵⁶
- 3. Immunization of tuberculin-negative individuals

Protection against exposure to disease is the ideal form of prevention.^{388,406} It presupposes thorough preemployment and ongoing case-finding programs among all who come in contact with children, including daycare center and school personnel, Sunday school personnel, teachers, health care workers, babysitters, household servants, food handlers, beauticians, and barbers. Numerous epidemics, miniepidemics, and mass exposures in neonatal nurseries have been traced to such infected individuals.

Immunization

Immunization against tuberculosis theoretically would be a tremendous boon to humanity, but in practice it has been fraught with very great difficulty. The impossibility of standardizing vaccines in the early days,^{45,219,648} differences in inoculation techniques and amount of bacteria inoculated, the lack of any clinically useful test reflecting the immune status of the individual, and the relatively slow course of the disease have handicapped epidemiologic studies. A number of new vaccines are in human clinical trials. These studies use surrogate markers of interferon, interleukin, and other cytokine responses as measures of vaccine take, because finding correlates of protection remains elusive.^{233,557}

BCG was developed in 1908 using an attenuated strain of *M. bovis*. In 1921, it first was administered orally to neonates and since then has been given to more than 4 billion people. BCG vaccine attempts to replace the potentially dangerous primary infection with *M. tuberculosis* with an innocuous primary infection with the bacillus of Calmette and Guérin, thus activating host cell-mediated immunity with minimal chance of causing progressive disease so that an infection with *M. tuberculosis* will be of the “reinfection” type.³⁵⁴

Difficulties in evaluation the BCG vaccine include variation in strain and differences in inoculation techniques and doses used. For almost

60 years, several BCG strains of different potencies were in use. The WHO, through its International Reference Preparation for BCG vaccine and through quality control testing, has helped decrease the gross variations in BCG vaccine found until recent years. Vaccination techniques and dosages are variable. Intradermal injection is the most precise technique. Multiple-puncture techniques are popular because they are easy, but less effective than intradermal injection. Oral vaccination, the original method of administration, largely has been abandoned because of poor results. The actual dose of BCG at present usually is approximately 10⁶ culturable particles. Because in animals large doses produce better resistance to challenge than small ones do, the largest convenient dose is used. However, in neonates, who have a higher incidence of untoward reactions, the customary approach is to halve the dose generally used in older infants and children to prevent local complications.

The usual local reaction to intradermal BCG vaccine is the development of a papule at the site of vaccination, and this papule reaches its maximal diameter (10 to 20 mm) in the sixth week. A small crust that may form on the papule detaches at about this time, with only a small ulcer remaining that may discharge a surprising amount of pus. Most ulcers are healed by the 10th week. A small scar is visible in over 80% of BCG-vaccinated individuals.^{308,536} Enlargement of the regional (axillary) lymph nodes occurs regularly and is painless, sometimes ending in calcification. Formation of an abscess with breakdown is a rare event, but it occurs more often in infants.

Untoward reactions to BCG rarely have been a problem.⁶⁶⁵ Fatalities caused by progressive disease have been reported in no more than 60 vaccine recipients (of an estimated 4+ billion), usually (but not always) children with well-documented immunodeficiency.^{78,145,191,215,486,491} No return of the attenuated strain to virulence has ever been noted. In countries where BCG is used routinely for immunization of neonates, osteomyelitis has been diagnosed in some 5 per 100,000 neonates. It usually becomes manifested when the child is between 5 and 33 months of age, when a tender swelling is noted near a joint; bone destruction is well localized and responds to conservative treatment.¹⁰¹ On the whole, BCG is one of the safest vaccines in use.

In many countries where BCG is given routinely, the incidence of HIV infection in adults and children is high.^{64,524} Reports of local and systemic complications from BCG vaccine in HIV-infected people are increasing, but the true magnitude of the interaction is not yet known.^{43,240,241,460,510} However, in more recent studies, the rate of adverse BCG reactions in HIV-infected children appears to be higher than thought previously.^{240,241} In most cases, BCG complications occur shortly after vaccination, but in one man with AIDS, adenitis as a result of BCG occurred 30 years after inoculation.⁵¹³ Routine treatment of patients with previous BCG vaccination who subsequently become immunocompromised is not recommended, but the clinician should be aware of previous BCG vaccination if signs or symptoms of mycobacterial infection occur.

The efficacy of BCG vaccines in humans has been evaluated in several large, well-controlled studies (Table 96.11). Three of these trials showed excellent protection, two showed mediocre protection, and two showed

TABLE 96.11 Summary of Eight Large Controlled Trials of BCG Immunization Against Tuberculosis

Subjects	Investigators	Intake Period	Vaccine Laboratory	Duration of Observation (y)	% Protection from BCG
North America: American Indians	Stein and Aronson, 1953	1935–38	Phipps	9–11	80
Chicago: infants	Rosenthal et al., 1961	1937–48	Tice	12–23	75

Modified from Sutherland, quoted by Eickhoff TC. The current status of BCG immunization against tuberculosis. *Annu Rev Med.* 1977;28:411–23.

^aInitial estimate of efficacy was 60%. Subsequently, when follow-up was extended to 9 to 14 y, the efficacy figure declined to 31%.

^bBCG vaccine given for the first time to children age 7–14 y.

BCG, Bacillus Calmette-Guérin.

little or no effect of BCG. Explanations for these differences in outcomes among trials must be sought in the quality and characteristics of the BCG vaccine used in the particular trial, the possible immunizing effect (in Georgia and Alabama) of infections with other mycobacteria,⁵⁸⁸ the possibly greater effectiveness of BCG vaccine in areas of high tuberculosis prevalence, and methodological variations among the trials.

The most recent large study of BCG effectiveness is the Chingleput study, started in 1968 near Madras, South India, an area where sensitization with nontuberculous mycobacteria is prevalent. People of all ages were vaccinated with one of two BCG vaccines or a placebo; only the incidence of adult-type pulmonary tuberculosis in the three groups was compared (i.e., not the forms usually found in children). During the ensuing years, no difference in incidence was noted among the three groups.²¹ This disturbing result has been the subject of several WHO investigations because BCG is one of the vaccines recommended for all children in the Expanded Program of Immunization sponsored by the WHO itself.⁵¹² Another study of neonatal vaccination with BCG in England reported very favorable results with BCG.¹³² Most countries administer BCG to infants. In some nations, multiple doses of BCG are used. The few data that are available on revaccination show a modest efficacy (9%).^{31,519} Revaccination with BCG is not recommended by the WHO. Higher effectiveness (up to 25% more effective than when BCG is given to neonates) is seen when BCG is given to school-aged children who never received BCG as infants.⁴⁹²

A group at the Harvard School of Public Health reviewed all published studies of BCG efficacy in a metaanalysis.¹¹⁶ Most published trials were not analyzed because of serious flaws in their experimental design or reporting. Among all trials and case-control studies included, the average protection against tuberculosis disease by various BCG preparations was 50%. The protective levels were higher for disease in children, particularly for meningitis and tuberculosis-associated death.^{115,661} However, ascertainment bias and lack of standardized case definitions render the results of these analyses very difficult to interpret. A more recent metaanalysis included 132 studies and indicated that there was evidence of measurable protection against intra- and extrathoracic TB for at least 10 years after vaccination.⁵ The BCG vaccines prevent many cases of tuberculosis in children, but the effect is quite variable. Variation in effectiveness of BCG in pulmonary tuberculosis has been seen across a number of trials. It has been hypothesized that these differences may be due to differences in BCG strains, overattenuation of BCG strains, interference in immunologic response caused by nontuberculous mycobacteria, and polymorphisms seen in human populations.³⁰⁵ That BCG vaccines are not an instrument of tuberculosis control also has become apparent because they do not prevent infection with *M. tuberculosis*, their protective effect is short lived, and vaccination of infants does little to prevent future cases of contagious tuberculosis among adults in a community.

The role of BCG vaccine in the United States today is very limited. The Advisory Committee on Immunization Practices of the US Public Health Service and the Advisory Council for the Elimination of Tuberculosis recommend BCG only for tuberculin-negative infants and children in the United States who (1) are at high risk for having intimate and prolonged exposure to persistently untreated or ineffectively treated adults with infectious pulmonary tuberculosis, cannot be removed from the source of infection, and cannot be prescribed long-term preventive therapy or (2) continuously are exposed to people with tuberculosis resistant to isoniazid and rifampin. A few experts, however, are more inclined toward the use of BCG in neonates who are at any risk for exposure to tuberculosis whatsoever.^{299,300,579,658}

The BCG vaccine has been used in healthcare workers in settings with high MDR-TB incidence to decrease their risk for nosocomial infection.⁶⁵ The utility of this strategy is unclear, but in regions where healthcare workers, many of whom are HIV infected, are continually exposed to MDR-TB, BCG vaccination may be a sustainable strategy.

Contraindications to the use of BCG for prevention of tuberculosis include congenital immunodeficiency, known HIV infection (in the United States), leukemia, lymphoma, and generalized malignant disease, as well as treatment with corticosteroids, alkylating agents, antimetabolites, and radiation. The WHO recommends giving BCG to asymptomatic HIV-infected infants who reside in areas with high tuberculosis rates.

Other Mycobacteria

W. Matthew Linam • Richard F. Jacobs

The definition of mycobacteria other than tubercle bacilli is quite confusing. Runyon¹⁵⁵ in his address to the International Conference on Atypical Mycobacteria probably defined them best: “Tubercle bacilli include *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium africanum*. Together with *Mycobacterium microti* (not pathogenic for humans), these organisms constitute the tubercle bacillus complex.” Any mycobacteria not listed in this group are considered to be in the “other” grouping. Mycobacteria other than those causing tuberculosis and leprosy were not recognized as causes of disease in humans until the 1950s.¹⁸⁹ The most common forms of the disease are chronic pulmonary disease resembling tuberculosis (occurring mainly in adults), cervical adenopathy in children, skin and soft tissue infection, and disseminated disease in immunocompromised individuals.¹³¹ In the mid-1980s, the incidence of infections with nontuberculous mycobacteria (NTM) increased markedly, probably because of the increased number of immunocompromised patients (e.g., because of AIDS, hematopoietic cell transplant, and organ transplantation) and the significant improvement in microbiologic methods for cultivating these organisms.^{215,218} With the continued proliferation of immunocompromised

patients because of AIDS and new treatment modalities that induce an immunocompromised state (e.g., organ transplantation, new immunosuppressive drugs), NTM probably will continue to remain important pathogens.

EPIDEMIOLOGY

NTM are ubiquitous in nature. They are found in soil, water, animals, milk,⁴⁹ and food. Of importance in some hospital-acquired infections or infections in immunocompromised hosts is the presence of the organisms in common tap water.^{18,67,118,181} Exposure to environments, especially soil, colonized by these organisms seems to be important for acquisition of disease in children. Organisms commonly found in soil include *Mycobacterium scrofulaceum*, *Mycobacterium flavescens*, *Mycobacterium avium* complex (MAC), *Mycobacterium gastri*, *Mycobacterium terrae*, *Mycobacterium fortuitum*, and *Mycobacterium chelonae*. Water is an important source for all of the previously named organisms and for *Mycobacterium kansasii*, *Mycobacterium marinum*, *Mycobacterium goodii*, and *Mycobacterium xenopi*. In a multi-site study evaluating

the presence of NTM in tap water, 78% of the water samples were positive for NTMs. The most frequently identified species were: *Mycobacterium mucogenicum* (52%), *M. avium* (30%), and *M. goodii* (25%).⁴⁶ A recent outbreak of rapidly growing mycobacterium (*M. chelonae*) in pediatric hematopoietic cell transplant patients was linked with the hospital water supply.⁸⁶

The estimated prevalence of NTM disease in the United States in the 1980s was 1.8 per 100,000 persons.¹³² More recent studies suggest that the prevalence has increased. A population study from Oregon in 2005 to 2006 estimated the prevalence at 7.2 cases per 100,000 persons.²¹ In a survey from the Centers for Disease Control and Prevention (CDC) from 1980, 35% of mycobacteria isolated in laboratories were nontuberculous.⁶¹ MAC (*M. avium* and *Mycobacterium intracellulare*) accounted for 66% of the nontuberculous isolates, followed by *M. fortuitum* (19%), *M. kansasii* (9%), and *Mycobacterium scrofulaceum* (6%). Two studies from 2009 showed a similar distribution of nontuberculous isolates. The distribution in the Australian study was MAC (48.5%), *Mycobacterium abscessus* or *M. chelonae* (13.2%), *M. fortuitum* (11.8%), and *Mycobacterium ulcerans* (5.9%).¹⁵ The distribution in a California study was MAC (47%), *M. abscessus* or *M. chelonae* (22%), and *M. fortuitum* (5%).¹⁴⁸ Some of the variation seen may be due to geographic differences.

Geography apparently has some bearing on the prevalence and type of these infections. MAC was seen most commonly along the coastal borders of the United States and in the states bordering Canada. The highest rates were seen in Hawaii (10.9 cases per 100,000 population), Connecticut (8.9 cases per 100,000 population), and Florida (8.4 cases per 100,000 population). High rates also were seen in Kansas and the desert Southwest, however, showing the widespread nature of this organism in causing disease. In contrast, *M. kansasii* was seen most commonly in the Midwest of the United States and almost never in the Southeast.⁵² *M. marinum* frequently was isolated from coastal areas, whereas *M. xenopi* was scattered across the United States, with 50% of cases found in just three states (Connecticut, Wisconsin, and California). Internationally, incidence rates of NTM infections in children range from 0.84 per 100,000 (Australia) to 3.1 per 100,000 (Germany).^{15,147} For all of the nontuberculous species, males and rural residents had a much higher incidence of infection.¹⁶¹ Extrapolation of these rates to determine disease patterns is not without problems, however. The number of mycobacterial isolates could be skewed easily by the presence of multiple isolates from a single patient, or it may just represent colonization. Nonetheless, these rates can help predict which species of NTM are most likely to be encountered in a particular geographic region.

The site of isolation from the human source can be helpful in determining the type of mycobacteria that may be involved in the disease process. MAC is responsible for lymphadenitis, particularly in children. MAC also is responsible for pulmonary disease and disseminated disease to bones and occasionally to the meninges. *M. kansasii* is associated most commonly with infections of pulmonary origin and disseminated lesions in adults; rarely, it is associated with adenitis and skin granuloma in children. *M. scrofulaceum* also causes lymphadenitis in children, and *M. marinum* is responsible for skin granuloma and ulcers after exposure to certain salt water beaches, swimming pools, and tropical fish tanks. The rapidly growing mycobacteria, such as *M. fortuitum* and *M. chelonae*, often cause skin and soft tissue infection and, rarely, pulmonary and disseminated disease in adults and children. A notable exception is the rapidly growing mycobacterium *M. abscessus*, which is the third most common NTM species recovered from respiratory specimens.⁶⁶ Healthcare-associated NTM infections have been reported in patients with long-term vascular catheters, peritoneal dialysis catheters, and various surgical procedures. Rapidly growing mycobacteria are frequently implicated. The source is often contaminated tap water.

A familial immune defect predisposing to disseminated NTM infection in childhood has been reported.¹⁰⁷ Interleukin (IL)-12 and interferon (IFN)- γ play an important role in the control of mycobacterial infections, primarily through upregulation of tumor necrosis factor (TNF)- α . Defects in either the synthesis or signaling pathways of these cytokines have resulted in disseminated NTM infections.⁴⁸ In addition, patients receiving anti-TNF- α therapy may be at increased risk for NTM disease, especially if they are receiving additional immune suppressive medications.²¹² In a recent study of patients receiving anti-TNF- α therapy, the

rate of NTM was 74 per 100,000 person-years compared to the background rate of NTM infection of 4.1 per 100,000 person-years.²¹¹

MICROBIOLOGY

Runyon and Timpe^{153,154,189} in their monumental work on NTM suggested a useful classification system based on three characteristics of the organisms: production of pigment, rate of growth, and colonial characteristics. The four groups are as follows: group I—photochromogens, which produce bright yellow to red pigment in the presence of light; group II—scotochromogens, which produce yellow to orange pigment in the dark; group III—nonphotochromogens, which are non-pigment producers; and group IV—rapid growers, which generally grow in less than 1 week. Kubica⁹⁹ published an updated version of Runyon's classification in 1978, and it was useful for many years. Subsequently, a more "simplified" classification based on the growth rates of the organisms alone was proposed.²¹⁵ More recently, reliable DNA sequencing, using the highly conserved 16S rRNA gene, has allowed for rapid recognition of new species. A sequence difference of greater than 1% usually indicates a new species. Currently, at least 160 NTM species have been identified.^{74,122,133,190}

The NTM still are differentiated by most clinical laboratories based on various morphologic, physiologic, and biochemical characteristics (Tables 97.1 and 97.2). The difficulty with identifying many of these organisms is their slow growth rates with standard techniques. Because antibiotic susceptibility varies for different species, it is important to identify organisms to the species level to ensure the appropriate therapy is chosen.⁶⁴ Results from identification and susceptibility testing are often delayed; therefore, this process should begin as soon as a NTM is cultivated and thought to be the responsible pathogen. In clinical medicine, serologic tests rarely are valuable for establishing a diagnosis in an individual patient. A study using humoral immunoglobulins against mycobacterial antigens failed to diagnose tuberculosis or nontuberculous adenitis in children.¹⁹⁴ Blood cultures for mycobacteria are best performed with the Isolator lysis-centrifugation system or the radiometric BACTEC 13A blood culture bottle.^{293,92} Blood collected in ethylenediaminetetraacetic acid or coagulated blood is unacceptable. Body fluids such as cerebrospinal fluid, pleural fluid, and peritoneal fluid can be inoculated directly into BACTEC or Septi-Chek broth, particularly if only small volumes are available. To aid in detection and growth, cultures should include both solid and broth media, whenever possible. Gene probes became commercially available in the late 1980s. They involve DNA probes complementary to species-specific sequences of rRNA for the identification of *M. tuberculosis*, MAC, *M. goodii*, and *M. kansasii*.⁶³

Polymerase chain reaction (PCR) assay has been evaluated for the routine detection of *M. tuberculosis* in the clinical laboratory and compared with fluorochrome smear and culture. Multiplex, real-time PCRs also have been developed to aid in the rapid identification of NTM. In a study by Kim and colleagues,⁹⁶ a multiplex, real-time PCR was developed capable of identifying 23 mycobacterial species and was tested using 77 reference strains and 369 clinical isolates. The test correctly identified all 189 (100%) isolates of the *M. tuberculosis* and 169 (93.9%) of the NTM isolates. Another multiplex, real-time PCR test using 314 clinical isolates had a 95% to 99% sensitivity and 99% to 100% specificity for distinguishing *M. tuberculosis* complex, MAC, the *M. chelonae*-*M. abscessus* group, the *M. fortuitum* group, and *Mycobacterium mucogenicum*.¹⁴⁸ The PCR testing offered by commercial laboratories at present is not approved by the US Food and Drug Administration for in vitro diagnosis. With newer isolation techniques and new technology such as DNA probes, the ability to diagnose these infections and understanding of the pathogenesis of the infections that these organisms produce should improve, as should the ability to treat these infections.

MANIFESTATIONS OF NONTUBERCULOUS MYCOBACTERIAL INFECTION IN CHILDREN

Lymphadenitis

Lymphadenitis is the most common manifestation of NTM infection in children, but it also occurs rarely in adults.^{43,103,110} All nodes in the

cervical chain can be affected, but the nodes of the submandibular region seem to be most commonly involved.^{45,116} The parotid gland also can be affected.³⁹ The differential diagnosis frequently centers on deciding whether a malignant process or a nonmalignant process is present. Nonmalignant processes to consider include mononucleosis, bacterial adenitis, cat-scratch disease, toxoplasmosis, tularemia, and *M. tuberculosis* infection.

Although most mycobacterial cases of lymphadenitis are caused by the nontuberculous organisms, the clinician also must consider *M. tuberculosis*.³⁵ No clinical features help the clinician discern between NTM infection and tuberculosis. The use of histopathology has been postulated to help differentiate between atypical and tuberculous infections.¹³⁸ In a retrospective study, the findings of ill-defined (nonpalisading) granulomas, predominantly sarcoid-like granulomas, or lack of significant caseation were seen more commonly with nontuberculous lymphadenitis. Additionally, nontuberculous infections had neutrophils predominantly in the center of the necrosis, whereas in tuberculous infections, neutrophils were scattered throughout the specimen.¹³⁸ A prospective study investigating these findings has not been published to date, and other authors have not noted similar patterns.¹²

In a Canadian study, the rate of NTM as a cause of lymphadenitis was 1.21 cases per 100,000 children, whereas the rate for tuberculosis was 0.3 cases per 100,000 children.¹⁷¹ Investigators from San Diego as well as other areas from around the world have reported a marked increase in the number of infections in immunocompetent children.^{59,139} In one study, the incidence increased from 1 case between 1987 and 1990 to 85 cases between 1991 and 1993.¹⁰² A recent Canadian study compared the incidence of NTM cervicofacial adenitis in children from 1994 to 1998 (25.1 per 100,000 hospitalizations) and 1999 to 2004 (107.4 per 100,000 hospitalizations) and showed a statistically significant increase. In a large study compiled by Lincoln and Gilbert¹⁰⁹ involving 243 children, more than 50% were younger than 3 years of age and 80% were younger than 5 years. Contact with NTM sources such as soil and water may account for the frequency of cervical lymphadenitis in young children.¹⁹²

Infections are caused mainly by MAC and *M. scrofulaceum*. A large prospective study spanning 32 years from 1958 to 1990 showed that

MAC has become the predominant etiologic agent and has surpassed *M. scrofulaceum* from earlier in the study.²¹⁷ Current data estimate that 72% of NTM lymphadenitis cases are caused by *M. avium*.¹³⁷ A series of 190 patients from India showed, however, that 60% of the nontuberculous adenitis cases were caused by *M. scrofulaceum*, followed by 40% by *M. avium-intracellulare*.⁸⁸ This difference may be due in part to differences in water chlorination. Additional causes of NTM lymphadenitis in children include *Mycobacterium haemophilum*,^{8,158} *Mycobacterium mageritense*,¹⁹¹ *M. fortuitum*,¹⁵⁰ and recently described *Mycobacterium heidelbergense*.⁷⁰

Most patients have no systemic symptoms and exhibit normal chest radiographs; other laboratory studies generally are not helpful. The mean duration of swelling is approximately 6 weeks. Affected lymph nodes are often unilateral and nontender. Over time, NTM infections involving superficial lymph nodes may develop a violaceous discoloration of the overlying skin. Nodes may spontaneously rupture or develop draining sinus tracts.

Currently, no NTM skin test is commercially available in the United States. All patients with suspected NTM lymphadenitis should have a tuberculin skin test placed. Children with NTM lymphadenitis can have a variety of reactions to tuberculin skin tests, ranging from 0 mm to greater than 10 mm of induration. Needle aspiration of an affected node can be a valuable diagnostic tool. Cultures for bacterial and mycobacterial etiologies should be performed, with recovery rates in children with cervical lymphadenitis ranging from 60% to 88%.^{10,16,80,91,221} The aspirate should be inoculated onto aerobic and anaerobic media and Sabouraud agar and mycobacterial media (Löwenstein-Jensen slants or Middlebrook media). Use of the BACTEC system can be helpful, especially in isolation of more fastidious species. Samra and colleagues¹⁵⁸ showed that the BACTEC radiometric system or MB Redox broth is superior to Löwenstein-Jensen media for isolation of *M. haemophilum*, and this may account for the increased identification of this organism. Mycobacteria can be isolated 12 to 17 days after inoculation.¹⁷⁷ PCR is being used with increasing frequency in the diagnosis in NTM lymphadenitis.^{31,137} More recently, preoperative diagnosis of *M. avium* lymphadenitis was accomplished with the use of PCR of gastric aspirates in two children.⁶⁹

The best treatment of lymphadenitis caused by NTM is complete excision of the involved lymph node.^{117,198} Incision and drainage without excision results in a high rate of secondary drainage, and subsequent excision of the remaining tissue is required for cure.^{5,157,164} Complete excision may not be possible when affected nodes are adjacent to large vessels or the facial nerve. In those situations, adjunctive antibiotic therapy may be necessary. The majority (59%) of clinicians manage NTM lymphadenitis by surgical excision followed by adjunctive antibiotics.¹³⁷ A randomized controlled trial involving 100 children with NTM cervicofacial lymphadenitis compared surgical excision to antibiotic therapy with clarithromycin and rifabutin.¹¹¹ Esthetic outcome was significantly better in the surgical group. Another small study showed successful nonsurgical management of deep cervical NTM lymphadenitis.⁷³

Pulmonary Infections

Reviews from the late 1970s showed that pulmonary disease caused by NTM usually was caused by *M. kansasii* and MAC.^{32,62,151} Historically, NTM pulmonary infections have occurred most commonly in men (ratios as high as 4:1), with most patients have underlying pulmonary disease such as chronic obstructive pulmonary disease (COPD). MAC infection most commonly occurred during the sixth decade, whereas *M. kansasii* infection occurred in individuals a decade younger. Two recent prevalence studies in the United States have shown that the epidemiology and clinical features have changed. An Oregon study estimated the 2-year prevalence of NTM pulmonary disease to be 8.6 cases/100,000 persons (20.4 per 100,000 for persons >50 years).²¹³ In a large multisite study, the age-adjusted annual prevalence was 5.4 cases per 100,000 persons.¹⁴⁰ Both studies show an increased prevalence of NTM pulmonary disease. This increase is most evident in women, especially those older than 60 years of age.¹⁴⁰ MAC was the most common isolate (80–87.5%), followed by *M. abscessus* or *chelonae* (6–12%).^{140,213} The epidemiology of NTM pulmonary infections in Europe is similar, but the rate of infections is lower.¹⁴⁹ Other species causing NTM pulmonary disease include *Mycobacterium simiae*, *M. kansasii*, *M. fortuitum*, *M. mucogenicum*, *Mycobacterium szulgai*, and *M. xenopi*.^{115,140,172,204} Underlying comorbidities such as COPD, bronchiectasis, and lung cancer were common, with bronchiectasis more common in women.^{140,213} Most common imaging findings were nodules (59%), bronchiectasis (39.7%), and cavitary lesions (8.5%).¹⁴⁰ Rare case reports of mediastinal mass lesions in children caused by NTM have been published.⁵⁴ NTM pulmonary disease is uncommon in children and most frequently seen in children with cystic fibrosis.³⁸

Patients with cystic fibrosis have been noted to have an increased incidence of infection with NTM with prevalence rates of 2% to 20%.^{4,78,79,95,165} In a large multicenter prospective prevalence study of NTM in patients with cystic fibrosis from France, which included 1582 patients, the prevalence of patients with at least one positive NTM culture was 6.6%.¹⁵² *M. abscessus* complex and MAC were the most common species responsible for both colonization and disease. Mycobacterial infections are seen more commonly in older patients with cystic fibrosis. The peak prevalence for *M. abscessus* was 11 to 15 years and 25 years for MAC.¹⁵² Frequent intravenous antibiotic use is a possible risk factor for colonization with NTM.¹⁹⁰ *M. abscessus* has emerged as a clinically significant pathogen in patients with cystic fibrosis, especially patients on steroid therapy for allergic bronchopulmonary aspergillosis.^{53,127,190} Persistent *M. abscessus* infection has been associated with lung function decline.⁵² Despite antibiotic therapy, less than a third of patients with *M. abscessus* clear their infection.¹⁴² Other organisms cultured from patients with cystic fibrosis include *Mycobacterium peregrinum*, *M. kansasii*, *M. fortuitum*, *M. chelonae*, and *M. xenopi*. Bacterial contamination, particularly with *Pseudomonas aeruginosa*, of the acid-fast bacilli cultures from patients with cystic fibrosis has been a major problem that has rendered isolation of mycobacteria more difficult.¹⁷⁴ Another confounding problem is the difficulty in differentiating infection from colonization in these patients.⁹⁵

The American Thoracic Society recommends radiographic changes (i.e., nodules, cavitary opacities, or multifocal bronchiectasis), isolation of multiple colonies of the same species, and the absence of other potential pathogens as criteria for the diagnosis of pathogenic infection

with NTM.³ Discernment is even more difficult in the setting of the chronic lung disease seen in patients with cystic fibrosis. Kilby and associates⁹⁵ suggest that repeated isolation of NTM associated with pulmonary cavities or infiltrates that do not improve with aggressive standard antibacterial treatment could indicate active mycobacterial disease in patients with cystic fibrosis.

Treatment of NTM pulmonary disease recommended by the American Thoracic Society requires prolonged courses using multidrug regimens. Drugs are administered for 18 to 24 months, with a minimum of 12 months of culture negativity required while receiving therapy. Treatment of MAC pulmonary infections involves clarithromycin or azithromycin, ethambutol, and rifampin. In fibrocavitary or other severe disease, streptomycin or amikacin may be added.⁶⁴ Treatment success is variable. The median efficacy of macrolide-based regimens reported in a review of 12 clinical trials was 56% (range, 26–71%).⁵⁵ A case was reported of a 7-year-old boy with leukemia in whom pneumonia with *M. xenopi* developed and was treated successfully with 2 years of therapy that included ethambutol and clarithromycin.¹⁰⁶ *M. simiae*, which has been isolated in adults with underlying pulmonary abnormalities, is the most drug-resistant of all the NTM, with some isolates resistant to all drugs tested.^{11,98}

Skin Infections

Mycobacterium marinum

M. marinum is photochromogenic and was identified as a pathogen in fish in 1926 by Aronson.¹⁰⁹ The natural reservoir for *M. marinum*, which requires a cool incubator (32°C [89.6°F]), is in fish and other cold-blooded animals. Skin lesions usually result from light trauma (abrasions) in swimming pools or other bodies of water when the surfaces of the pool are colonized by *M. marinum*.^{41,124} Fish tanks also have been implicated and generally involve the upper limb or a finger.^{9,185} Most cases occur in children aged 10 to 16 years old. The most common sites are the elbows, knees, and ankles. Cooler superficial portions of the body are affected most frequently. Other exposed body areas can be involved, depending on what part of the body has made contact with the water containing the mycobacterium (e.g., the nose in divers).¹²⁵ Lesions are usually solitary but may have a sporotrichoid pattern. Regional spread of lesions has been reported.¹⁷⁹

The incubation period from exposure to formation of a small, indurated papule that ulcerates generally is 3 weeks. The lesion then crusts and forms a granuloma with a small crater. The lesions usually are painless and resolve in several months; occasionally, they can last longer. In contrast to other mycobacterial diseases, regional nodes are usually not involved. Infection with this organism usually is benign, but it frequently results in the conversion of a purified protein derivative stabilized with Tween (PPD-T) test to positive.¹⁰⁹ Generally, only a few organisms may be isolated in some granulomas.

M. marinum is usually susceptible to rifampin, ethambutol, clarithromycin, and trimethoprim-sulfamethoxazole and intermediately susceptible to doxycycline. Treatment regimens usually include two active agents. Treatment of *M. marinum* has been successful with rifampin and ethambutol.^{196,214} Other studies have shown success with a combination of clarithromycin and rifampin.⁹ The duration of therapy, according to the literature, varies from several weeks to 18 months. Generally, response to therapy is rapid, and treatment should be continued for 4 to 6 weeks after clinical resolution.⁴⁷

Mycobacterium ulcerans

Infections caused by *Mycobacterium ulcerans* result in chronic necrotizing cutaneous ulcers known as Buruli ulcers. *M. ulcerans* and Buruli ulcer are covered in greater detail in Chapter 98. In 1948, MacCullum¹¹⁴ reported the first cases of disease caused by *M. ulcerans*. Most cases have occurred in remote, tropical, or subtropical areas of the world, including parts of Africa and Australia.^{113,146} Cases also have been reported in Mexico.¹⁰⁹ Most patients harboring this organism are in otherwise good health without underlying immunodeficiency.³³ Scraping of the skin by thorns or pieces of wood or insect bites have been implicated as possible routes of inoculation in many of the cases. The natural reservoir for *M. ulcerans* is unknown. One report suggests the spines of a tall prickly grass known as *Echinochloa pyramidalis* as a reservoir.¹⁸⁰

An Australian study found evidence that mosquitoes may play a role in the transmission of *M. ulcerans*.¹⁰⁴ The lesions caused by *M. ulcerans* occur mainly on the cooler superficial portions of the body. The organism is fastidious, with growth requiring 6 to 12 weeks and seen only between 25°C and 33°C (77°F–91.4°F).

The incubation period is approximately 3 weeks. Disease forms include: papules, nodules, plaques, edema, and ulcers. Lesions often begin as nodules or plaques and can progress to ulcers. Ulcers can become large with significant tissue destruction. Occasionally, disease spreads to bone resulting in osteomyelitis. Complications can result when the infection extends into adjacent tissues and organs resulting in tissue destruction. Disseminated infection in an immunocompetent child, along with the development of multifocal osteomyelitis, has been described.⁸⁰ Healing frequently results in scarring and fibrosis, which in the setting of large or deep ulcers can result in functional limitations and deformities. Treatment for Buruli ulcers includes antibiotics and surgery. Surgery is typically reserved for removal of necrotic tissue, coverage of skin/tissue defects and restoration of function. Recommended antibiotic regimens include rifampin in combination with an aminoglycoside or clarithromycin and is usually administered for at least 8 weeks.

Other *Mycobacteria* in Skin Disease

A study of archived skin biopsy specimens using PCR for NTM identified additional NTM skin infections.¹⁹⁵ *M. haemophilum* was the most common organism identified. *M. haemophilum* has produced painful subcutaneous nodules in immunocompromised patients, particularly patients with renal transplants.^{42,216} *M. chelonae* has been found to be a cause of disseminated cutaneous infection.²⁰⁰ Steroid use is the predisposing factor for infection with this organism. *M. fortuitum-chelonae* complex has been responsible for superficial skin abscesses in children.¹⁴ *M. fortuitum* was implicated as the cause of cutaneous lesions in a child involved in a motor scooter accident, with the subsequent development of lesions at the site of knee lacerations; regional adenopathy of the inguinal nodes also developed.¹⁶⁹ A recent outbreak of cutaneous hand and foot infections in 29 children caused by *M. abscessus* was linked to a school swimming pool.¹⁷³ *M. avium* has been isolated from an eyelid abscess.¹⁶³ Contaminated pedicure footbaths have been implicated in outbreaks of NTM skin infections, including a recent outbreak from *Mycobacterium bolletii* and *Mycobacterium massiliense*.²⁰⁷ NTM skin infections also have occurred at insulin injection sites, acupuncture sites, and filler injection sites, with many of these caused by rapidly growing mycobacteria.^{105,178} Treatment of cutaneous disease caused by these organisms is difficult at best. Four- or five-drug therapy has been tried, but with poor results.

Other Sites of Infection

Although infections involving lymph nodes, lungs, and skin are the most frequent sites of infection, NTM infections have been reported from nearly every organ system. Carpal tunnel syndrome in adults has been reported as being caused by *M. szulgai*, an uncommon scotochromogenic mycobacterium.¹⁸³ In a review of 21 cases of *M. szulgai*, pulmonary disease was most common, with disseminated disease more common in immune-suppressed patients.¹⁹⁷ Effective treatment included debridement, ethambutol, and rifampin. Other infections in humans include choroiditis,³⁴ panniculitis,¹⁵⁹ parotitis,²⁹ genitourinary tract infection,^{17,188} and synovitis.¹⁸⁴ Ear infections with NTM also have been reported, as has mastoiditis.^{56,130,182} Importantly, infection of Broviac catheters in pediatric patients with leukemia and hemodialysis and peritoneal dialysis catheters has been described.^{24,28,106,166,193} In all cases, removal of the catheter was required for resolution of the infection. NTM are a rare cause of ventriculoperitoneal shunt infections including infections in children.^{20,187} *M. fortuitum* is the most common species identified. Patients frequently present with subacute meningitis. Catheter removal is imperative.

Acquired Immunodeficiency Syndrome and Nontuberculous *Mycobacteria*

Before the availability of combination antiretroviral therapy (cART), NTM infections, most commonly MAC, were the second most common

opportunistic infections in children in the United States with human immunodeficiency virus (HIV) infection. The incidence rate in the pre-cART era was 1.3 to 1.8 episodes per 100 person-years.^{60,129} Approximately 6% of adults and 4% of children with AIDS reported to the CDC had disseminated MAC infection as the AIDS-defining disease.²² Autopsy studies show that MAC infection is present in 20% to 50% of adult HIV-infected patients.^{145,206,209} In a retrospective study from 1990 to 1996 in New York City, 26% of children had evidence of MAC infection at the time of their deaths.⁸⁹ MAC infection was thought to be the cause of death in 13% of the 54 children with HIV infection, and the mean age at death was 7.8 years. More than 70% of children with MAC and AIDS had evidence of disseminated disease. Almost all had CD4⁺ counts less than 100 cells/mm³. Since the availability of cART, incidence of MAC has decreased to 0.14 to 0.2 episodes per 100 person-years.^{60,129}

In the CDC study, MAC was the NTM most commonly isolated in HIV patients. In adult studies, *M. kansasii* and *M. scrofulaceum* have been identified as causes of infection, but the incidence of infection is low.^{44,83} In patients with HIV, *M. fortuitum* complex is the most frequently isolated rapidly growing mycobacteria and typically causes lymphadenitis and pulmonary disease.¹⁴³ *Mycobacterium genavense* has been shown to cause infection in children with HIV infection with the organism identified in stool and lymph node specimens.¹²⁸

Clinical findings included failure to maintain growth curves, anorexia, persistent or recurrent fever, fatigue, and abdominal pain. MAC has been shown to infect the esophagus, stomach, and intestine of pediatric patients with AIDS.⁹⁰ Patients with extensive MAC infection of the small and large intestines have severe, persistent diarrhea. Respiratory symptoms are uncommon. Clinical findings may include hepatomegaly, splenomegaly, or lymphadenopathy. Bone marrow suppression also may occur. The median age at diagnosis was 46 months, with a median of 9 months elapsing between the onset of symptoms and positive cultures. When NTM infection was diagnosed in these patients, they survived less than 10 months. Blood cultures have 90% to 95% sensitivity in detecting disseminated MAC infection in adult patients with AIDS.⁷⁶ Infection is also confirmed by isolation of MAC from a normally sterile body site such as lymph node or bone marrow. Isolates should be tested for susceptibility to azithromycin and clarithromycin.

For treatment of MAC infection in HIV-infected children, combination therapy is recommended.¹⁷⁰ Clarithromycin or azithromycin and ethambutol should be included. Clarithromycin/ethambutol has been shown to be more effective than azithromycin/ethambutol in one randomized trial.²⁰² Rifabutin can be added as a third drug, but its use is controversial. The decision to start rifabutin should balance the degree of immune suppression and the extent of infection with the effect increased cytochrome P450 has on other medications. Lack of clinical response after 8 to 12 weeks of treatment suggests treatment failure. Repeating susceptibility testing and initiating a new combination regimen based on the results are recommended. Additional antibiotics to consider include rifabutin, amikacin, and quinolones. The use of granulocyte colony-stimulating factor as an adjunct to antimicrobial therapy for disseminated MAC infection has been reported,¹³⁴ but additional data are needed to determine the usefulness of this agent. Immune reconstitution inflammatory syndrome has been reported in adults and children with MAC infection receiving cART.^{37,167}

Secondary prophylaxis is recommended for all children with a history of disseminated MAC infection. Clarithromycin is recommended in combination with ethambutol, with or without rifabutin. In most situations, secondary prophylaxis is lifelong. Guidelines are available for discontinuing prophylaxis in children who have completed appropriate therapy, are without evidence of ongoing infection, are stable on cART, and have sustained recovery of their CD4⁺ cells above the threshold for initiating primary prophylaxis.¹⁷⁰

The US Public Health Service and the Infectious Disease Society of America have published guidelines for the prevention of opportunistic infections, including disseminated MAC.¹⁷⁰ These guidelines incorporate age-specific CD4⁺ counts at which primary prophylaxis should be used: children 6 years of age or older, fewer than 50 cells/mm³; children 2 to 6 years old, fewer than 75 cells/mm³; children 1 to 2 years old, fewer than 500 cells/mm³; and children younger than 1 year, fewer than 750

cells/mm³. Before initiating prophylaxis, patients should be evaluated for disseminated MAC infection by obtaining a blood culture for MAC. The use of clarithromycin or azithromycin for primary prophylaxis is recommended for adults and children with advanced immunosuppression. In HIV-infected children older than 2 years of age, primary prophylaxis may be discontinued once they are stable on cART (>6 months) with sustained immunologic response for over 3 months (children age ≥6 years, >100 cells/mm³; children age 2–6 years, >200 cells/mm³). Rifabutin can be used as an alternative agent; although poor efficacy and side effects limit its utility.^{170,175} Combination therapy for prophylaxis is not recommended.

The emergence of resistance is a concern with the MAC prophylactic regimens in patients with AIDS. In some trials, 9% of adults receiving azithromycin prophylaxis and 5% of adults receiving clarithromycin prophylaxis had breakthrough MAC bacteremia. Of these cases, 11% and 58% of the azithromycin and clarithromycin, respectively, breakthrough isolates were macrolide-resistant.^{6,75}

ORGANISMS SEEN IN CHILDREN

Specific organisms and treatment guidelines are discussed in the following sections. Table 97.3 provides a quick guide to some of the more commonly used antimycobacterial agents.

Mycobacterium avium-intracellulare Complex

MAC consists of *M. avium* and *M. intracellulare*. *M. avium* was recognized in 1890 as the causative agent of disease in chickens.²¹⁶ *M. intracellulare* was designated in 1967 and at the time was difficult to distinguish routinely from *M. avium*, thus the name *M. avium-intracellulare*. Today, with the use of DNA probes, most seroagglutination types have been discerned between the two groups. *M. avium* is the most common NTM causing disease in humans, but isolates from environmental sources are more likely to be *M. intracellulare*. Both organisms can be found in birds, soil, dust, and fresh or salt water. Infections caused by MAC

strains isolated from adult patients with AIDS could be identified as either serotype 4 or 8, in contrast to patients without AIDS, in whom no predominant serotype has been identified.^{94,219} Nearly all isolates of MAC from patients with AIDS have been identified as *M. avium*; in patients without AIDS, the rate of *M. avium* is approximately 55%, and the rate of *M. intracellulare* is 32% to 40%.^{68,219}

In a study of 56 isolates from pediatric patients involving sequence analysis of the ribosomal internal transcribed spacer, Hazra and colleagues⁷⁷ showed that the closely related Mav-B and Mav-A sequevars caused most disease. Patients from geographically diverse areas of the United States (i.e., Boston, Miami, and Los Angeles) had isolates with closely related patterns. The finding of related strains causing disease in epidemiologically unrelated patients is most consistent with two hypotheses: a similar subset of *M. avium* strains is more virulent and more likely to cause disease in humans, or pathogenic strains are more prevalent in the environment.

These organisms are slow-growing, obligate aerobes that require 2 to 6 weeks for colony formation on solid media. MAC infection is diagnosed most commonly by culture of blood, bone marrow, or tissue. These organisms grow on routine bacterial media, but growth is achieved best on selective mycobacterial media, such as Löwenstein-Jensen medium or Middlebrook 7K10 and 7K11 agar. Colonies usually are smooth but may be rough and can be transparent or opaque. Nucleic acid hybridization probes using target sequences of ribosomal RNA are available commercially for rapid identification of clinical isolates.^{108,126}

In children, lymphadenitis is the most common manifestation of MAC. Please refer to the section on lymphadenitis for more information. In non-immunocompromised adults, lung disease has been the major manifestation of MAC infection. Most investigators thought that MAC infection occurred mainly in patients with deficient immunity or underlying lung disease; however, later reports seemed to indicate that normal adult hosts are at risk for development of infection with MAC and that rates are increasing.^{87,141} The incidence of NTM lung disease in postmenopausal women has increased over the last 20 years, especially

TABLE 97.3 Antimycobacterial Agents

Drug	Dosage	Form
Amikacin (A)	15–30 mg/kg/day divided 3 times daily	IV or IM
Azithromycin (Z)	500 mg bid (adults/adolescents); 10–12 mg/kg/day (children)	PO
Cefoxitin (X)	80–160 mg/kg/day divided 4 to 6 times daily	IV or IM
Ciprofloxacin (C)	20–30 mg/kg/day divided 2 times daily (adults only in United States)	PO or IV
Clarithromycin (CL)	15–30 mg/kg/day divided 2 times daily	PO
Clofazimine (CLO)	1–2 mg/kg/day	PO
Doxycycline (D)	2–4 mg/kg/day divided 2 times daily (>8 yr old)	PO, IV
Ethambutol (ETB)	15 mg/kg/day	PO
Ethionamide (ETH)	15–20 mg/kg/day divided 2 times daily	PO
Imipenem (IMP)	60–100 mg/kg/day divided 4 times daily	IV
Isoniazid (I)	5 mg/kg/day	PO
Pyrazinamide (PZA)	15–30 mg/kg/day	PO
Rifabutin (RIB)	5–10 mg/kg/day; maximum 300 mg/day	PO
Rifampin (RIF)	10–20 mg/kg/day once or divided 2 times daily	PO or IV
Streptomycin (S)	20–30 mg/kg/day	IM
INFECTIONS		
Disseminated MAC: HIV infected: CL (or Z) + ETB (± RIB)		
MAC lung disease: CL (or Z) + ETB + RIF ± S or A (severe or cavitary disease)		
<i>Mycobacterium abscessus</i> : CL or Z + one or more of A, X, or IMP		
<i>Mycobacterium chelonae</i> : CL alone (skin disease), two or more of the following: CL, linezolid, IMP, or tobramycin (invasive disease)		
<i>Mycobacterium fortuitum</i> : two or more of the following: CL, C, A, X, IMP, or TMP-SMX		
<i>Mycobacterium kansasii</i> : RIF + ETB + I		
<i>Mycobacterium marinum</i> : ETB + RIF, or CL + RIF		

Data from references 64, 67, 83, 106, 107, 155, 194, 204, 216, 218.

HIV, Human immunodeficiency virus; MAC, *M. avium* complex; TMP-SMX, trimethoprim-sulfamethoxazole.

in slender women with scoliosis or pectus excavatum.²³ Case reports involving children are lacking in detail because they usually appear within discussions of adult patients.¹⁴⁴

Pediatric case reports of disseminated disease caused by MAC have appeared in the literature. Children have had ulcerative lesions of the colon⁴⁰; mesenteric disease with abscess formation¹⁶³; hematogenous spread to the liver, spleen, kidneys, and adrenal cortex; lesions of the epididymis¹⁷⁶; bone lesions¹⁹⁹; and skin lesions. Disseminated osteomyelitis rarely is caused by NTM, but if it occurs, *M. intracellulare* most commonly is isolated.^{30,97} Septic arthritis also has been reported in association with osteomyelitis.⁵⁸ Immunocompromised patients with disseminated MAC infection historically require multiple-drug therapy, including a combination of azithromycin or clarithromycin and ethambutol. Rifabutin is frequently added as a third agent.⁶⁴ Some reports indicate, however, that disseminated disease in HIV-infected patients may respond to only two agents, as mentioned earlier in the discussion of AIDS patients. The addition of other agents may be necessary because of the high incidence of resistant organisms. A preliminary report showed that IFN- γ might be effective when combined with conventional therapy in some patients who are refractory to standard chemotherapy alone.⁸²

Bacterial peritonitis is a common occurrence in patients regularly undergoing ambulatory peritoneal dialysis for chronic renal failure. Reports of NTM causing peritonitis have been noted.^{71,135,208} In cases involving NTM with foreign bodies, such as Tenckhoff catheters, the development of infected sinus tracts is frequent. Additionally, antituberculous drug regimens in these cases generally are unsuccessful. Although the mycobacteria were sensitive to the agents used, the patients continued to have sinus tract drainage without improvement, even after removal of the foreign body.

Mycobacterium scrofulaceum

M. scrofulaceum has many characteristics similar to those of *M. avium* and *M. intracellulare* and can be found in soil, water, and dairy products. This organism is associated most commonly with lymphadenitis in children 1 to 5 years old and rarely causes other manifestations in humans. Skin and bone lesions have been reported in two children chronically infected with *M. scrofulaceum* for 10 years.^{50,205} Disseminated disease caused by *M. scrofulaceum* is rare, but was recently reported in a child with IFN- γ receptor 1 deficiency.¹¹⁹ Few data are available on chemotherapeutic agents for treatment of infection with this organism. Based on susceptibility patterns, three or more drugs may be necessary for treatment of serious disease. Lymphadenitis can be cured with complete excision of the lymph node.

Mycobacterium kansasii

Of the photochromogens, *M. kansasii* is the one most commonly isolated in humans. It is also the second most commonly identified NTM causing disease in the United States. In contrast to *M. avium-intracellulare* and *M. scrofulaceum*, *M. kansasii* rarely is isolated in soil but has been cultured from water and milk.^{26,27} Chronic pulmonary infection is the most common manifestation of this disease and is seen mainly in adults, particularly adults with AIDS. A survey from Israel of 56 adults with *M. kansasii* pulmonary infection showed that 64% occurred in men, 59% had underlying lung disease, and none was infected with HIV.¹⁶⁸ Pulmonary disease occurs infrequently in children. Some children have a course similar to that of adults, with underlying pulmonary disease caused by previous tuberculosis or chronic pulmonary disease.^{13,123} The clinical presentation of *M. kansasii* lung disease is similar to that of *M. tuberculosis*, including cavitory infiltrates and more frequent involvement of the upper lobes, although bilateral disease, pleural effusions, and lymphadenopathy are less common.¹⁶⁸ In contrast, other children have acute symptoms of classic bacterial pneumonia with an abrupt onset of fever and sputum production and lung consolidation on physical examination and radiographs.^{13,25}

In contrast to some other nontuberculous organisms, *M. kansasii* is sensitive to most of the antituberculous drugs, particularly rifampin. Most authorities recommend the use of three drugs, including rifampin, isoniazid, and ethambutol. The treatment course usually requires a minimum of 12 months of negative sputum cultures, with therapy for 24 months needed in some patients. A study of 18 patients showed that

thrice-weekly clarithromycin, ethambutol, and rifampin were effective, with a mean follow-up of 46 months.⁶⁵ Patients with AIDS and *M. kansasii* infection have responded to this three-drug regimen, but the total duration of therapy is unknown at this time. In children with AIDS, the diagnosis of *M. kansasii* infection is rare, and the clinical response to therapy has been poor.⁸⁴ Cases have been reported in other immunocompromised children, including a 7-month-old boy with disseminated *M. kansasii* infection and numerous organisms found in his spleen at autopsy.¹²¹ *M. kansasii* also has been reported to cause meningitis; the patients died despite the use of antimycobacterial therapy.^{85,160} In another report, an 18-month-old previously healthy boy developed chronic septic arthritis of the ankle with adjacent osteomyelitis of the distal tibia²¹⁰ resulting in significant bone destruction.

Mycobacterium mageritense

Buchholz and coworkers¹⁹ reviewed infections with *M. mageritense* in the United States from 1993 to 1995. Only 1 of 73 patients was younger than 10 years. This patient had cervical lymphadenitis and was cured with surgical excision alone. This organism, which frequently is overlooked on standard Löwenstein-Jensen egg medium, grows at 25°C to 37°C (77° to 98.6°F). The organism is slow-growing, and it may require 8 to 12 weeks for colonies to become visible on solid media. The BACTEC system was shown to be superior in isolating *M. mageritense* in one study of children with lymphadenitis.⁸¹ Bone marrow involvement also was described in a patient with chronic granulocytic leukemia.⁵¹ PCR may improve the identification of this organism. The study by Buchholz and colleagues¹⁹ showed that prolonged combination therapy with isoniazid, rifampin, ethambutol, and pyrazinamide after surgical excision was effective in some cases.

RAPIDLY GROWING MYCOBACTERIA

NTM that form colonies on subculture within 7 or fewer days are referred to as *rapidly growing mycobacteria*. The *M. chelonae-abscessus* group consists of *M. chelonae*, *M. abscessus*, *M. bolletii*, and *M. massiliense*. The *M. fortuitum* complex consists of *M. fortuitum*, *M. peregrinum*, and biovariant 3.^{101,72} Multilocus DNA sequencing may be needed to differentiate rapidly growing mycobacteria to the species level.^{1,223} Patients typically have an underlying condition such as immune suppression or cystic fibrosis and may have a catheter or other implanted device. The most frequent manifestations of rapidly growing mycobacteria include pulmonary infections, bloodstream infections, skin and soft tissue infections, osteomyelitis, device-associated infections, and disseminated disease.^{143,72}

M. abscessus, as stated earlier, is related closely to *M. chelonae* but should be designated as a separate species.¹⁰¹ Manifestations of *M. abscessus* infection usually involve pulmonary, bloodstream, cutaneous, or occasionally disseminated disease.^{66,201,72} *M. abscessus* is the most common rapidly growing mycobacteria isolate causing pulmonary disease.⁶⁶ Underlying conditions such as bronchiectasis, gastroesophageal disorders with chronic vomiting, and cystic fibrosis are frequently present. Multilobar nodular bronchiectatic disease is the most common presentation. Cutaneous disease is often related to surgery or trauma and manifests as purple nodules. Maxson and associates¹²⁰ reported a case of osteomyelitis caused by *M. abscessus*.

Wallace and associates²⁰⁰ provided the largest series of patients with skin, soft tissue, and bone involvement with *M. chelonae*, which is the primary clinical manifestation. Steroid use seemed to be the factor associated most commonly with the development of disease. Adult renal transplant patients also have been described with skin and subcutaneous tissue involvement caused by *M. chelonae*.³⁶ *M. chelonae* has also been described as an etiologic agent for otitis media, probably from contamination of ear, nose, and throat instruments with colonized water sources.¹¹² Cases of keratitis caused by *M. chelonae* have been reported after laser in situ keratomileusis (LASIK).^{57,220} Pulmonary disease is less common.⁶⁶ With the improved ability to distinguish *M. abscessus* and *M. chelonae*, many isolates that were once identified as *M. chelonae* may now be identified as *M. abscessus*.⁷²

M. fortuitum complex is one of the most frequently isolated rapidly growing mycobacteria and causes a range of diseases, including

pulmonary, wound, lymphadenitis, and catheter infections.^{143,72} *M. fortuitum* and *M. chelonae* have been implicated in sternal wound infections and endocarditis and have occurred in outbreak-type settings.^{100,156,186} Patients responded to surgical debridement and amikacin with cefoxitin. A case series from Hong Kong reported successful treatment of *M. fortuitum* sternotomy infections with the use of a single daily dose ofloxacin as monotherapy in three patients.²²² Pulmonary disease with findings similar to those in *M. abscessus* occur in patients with *M. fortuitum*, but primarily in patients with gastroesophageal disorders with chronic vomiting.⁶⁶

Other rapidly growing mycobacteria include *M. mucogenicum*, which is commonly isolated in cancer patients. In this population, *M. mucogenicum* is the rapidly growing mycobacteria most frequently associated with bloodstream and catheter-associated infections.⁷² An outbreak of *M. mucogenicum* catheter-associated bloodstream infections occurred in eight pediatric hematology and oncology patients.¹⁶⁶ Six of the patients were successfully treated with catheter removal alone. *Mycobacterium neoaurum* also has been associated with catheter-associated bloodstream infections in immune-suppressed patients, including children.²⁰³ *Mycobacterium smegmatis*, which resembles *M. fortuitum*, is a rapidly growing mycobacterium responsible for skin and soft tissue infections.²⁰¹ A case of disseminated infection has been reported in a child with inherited IFN- γ receptor deficiency.¹³⁶ *M. massiliense*, which is a rapidly growing mycobacterium closely related to *M. abscessus*, was associated with an outbreak of intramuscular injection-associated soft tissue infections in adults and children.⁹⁵ *Mycobacterium septicum* is a recently described rapidly growing mycobacterial species associated with catheter-related bacteremia.¹⁶² *Mycobacterium wolinskyi* is an uncommon cause of posttraumatic and postsurgical wound infections and osteomyelitis.⁷ As our ability to detect and distinguish different mycobacterial species improves, the number of mycobacterial species implicated in human infection will likely continue to increase.

Treatment of rapidly growing mycobacteria usually requires combination therapy involving at least two agents. Because susceptibility differs across species, these bacteria should be identified to the species level and treatment based on susceptibility testing. In general, skin and soft tissue disease should be treated for at least 4 months and bone disease for at least 6 months. Surgery may be required for extensive disease. For infections involving implants, the foreign body should be removed. Pulmonary disease often is difficult to treat, but a goal of at least 12 months of negative sputum is reasonable.⁶⁴

Leprosy and Buruli Ulcer: The Major Cutaneous Mycobacterioses

98

Andrea T. Cruz

Mycobacterial infections in humans date to at least the 10th millennium BCE, with evidence of tuberculosis in Neolithic skeletons from Heidelberg, Germany,¹⁵ Egyptian mummies,²⁷⁹ and from pre-Columbian Mesoamerica.⁷⁷ Evidence of lepromatous leprosy has been found in burials in India dating back to 2000 BCE, correlating with Vedic scriptural references to leprosy.²⁶⁹ Although the origins of mycobacterial infections in humans are unknown, most authorities speculate that domestication of animals in the Neolithic era promoted the transmission of mutants of *Mycobacterium tuberculosis* from livestock to humans. The origins of leprosy and Buruli ulcer and their respective etiologic agents are understood less well but may involve interplay among nontuberculous mycobacteria, animals, and humans.²⁹⁴ After tuberculosis, leprosy and Buruli ulcer are the second and third most common mycobacterial infections in humans. Leprosy and Buruli ulcer are the two most common cutaneous mycobacterioses.

Tuberculosis and other cutaneous mycobacterial infections are discussed in Chapters 96 and 97. This chapter is devoted to the two cutaneous mycobacterioses that are of greatest medical importance: leprosy and Buruli ulcer.

LEPROSY

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae* that principally affects the cooler parts of the body, especially the skin, upper respiratory tract, testes, eyes, and superficial segments of peripheral nerves. The World Health Organization (WHO) reported that in 2013 there were 215,000 incident cases and 180,000 prevalent cases.³⁷⁷ Many authorities consider that the total global prevalence of patients with active leprosy is much higher (1.5–2 million),¹¹ however, and are

underreported because of the stigma associated with leprosy.¹³⁹ Several million more patients experience serious sequelae.¹⁸²

In the Middle Ages, leprosy was common in Europe, reported in up to one quarter of skeletons in one ordinary (nonleprosy colony) Danish village cemetery.²⁷ European emigration and the West African slave trade, rather than crossing from Asia via the Bering Strait, likely introduced leprosy to the New World. The Silk Road may have then spread leprosy from Europe to China.²²¹ At least two foci in the United States were established in the 19th century by specific immigrations: Asians brought leprosy to the Hawaiian Islands and started an epidemic in the highly susceptible Hawaiians²²⁴ and Scandinavians introduced leprosy into the northern Midwest region of the United States.¹⁹¹

Patients with leprosy frequently experience severe stigmas. This has been noted in the Old Testament (Leviticus 13:4) and in 8th century BCE Chinese literature.³¹⁵ Similarly, the *Laws of Manu* (India, circa 1500 BCE) punished persons marrying into families with leprosy.³³ Although suicide was considered a sin under Hinduism, leprosy was an exception.¹³⁹ The stigma persists to the modern era. In 2009, the chairman of India's human rights commission recommended prosecuting leprosy patients if they had children.³⁷ Continuing efforts must be made to minimize the stigma peculiarly associated with leprosy. To help achieve this goal, the Fifth International Leprosy Congress in 1948 adopted a resolution to abandon the word *leper* for the leprosy patient.¹⁷⁹ Some physicians prefer Hansen disease as a synonym for leprosy.

Organism

M. leprae is a species in the order Actinomycetales and the family Mycobacteriaceae. This bacillus was seen first by Hansen in 1873 in Bergen, Norway, in lepromas from Norwegian patients, and this organism was the first reported bacterium causing chronic disease in humans.

M. leprae is an acid-fast bacillus 0.3 to 0.5 μm wide by 4 to 7 μm long. The acid-fastness of *M. leprae* is weaker than that of other mycobacteria. Viable *M. leprae* organisms stain solidly, but degenerating bacilli first stain irregularly, then become granular, and eventually lose acid-fastness completely. The persistence of bacillary carcasses can be verified by silver staining techniques.³⁵⁰ Because *M. leprae* still cannot be cultivated, identification depends on criteria other than those used routinely for cultivable mycobacteria. Current criteria for *M. leprae* are the following: (1) it does not grow on routine laboratory media; (2) it infects the footpads of mice in a characteristic manner^{180,309}; (3) acid-fastness is extractable with pyridine⁵³; (4) the organism invades nerves of the host; (5) suspensions of dead bacilli produce a characteristic pattern of reactions when injected into the skin of patients (lepromin reaction) with the various clinical forms of leprosy; (6) it produces the species-specific antigen phenolic glycolipid-1 (PGL-1)¹⁰⁵; and (7) it exhibits species-specific DNA sequences.³⁶⁵

Gene deletion and decay have markedly limited the metabolic activities of *M. leprae* and may contribute significantly to failure to cultivate the organism and to its long generation time in the mouse footpad (14 days).^{29,86} Localization of infections to the cooler parts of the body,²⁶ selective growth in the footpads of immunologically intact mice and in the ears of hamsters, and the high susceptibility of the armadillo (central body temperature of 32°C to 35°C [89.6°F to 95°F]) to disseminated infections all suggest that the optimal temperature for growth of *M. leprae* is less than 37°C (98.6°F).²⁰¹

Transmission

The modes of transmission of *M. leprae* in nature have not been fully established. The frequency in children of a single early lesion in skin that usually is covered by clothing argues against the development of such lesions at the site of contact with *M. leprae*.¹⁸ For many years, skin-to-skin contact between the patient and healthy subjects was considered the most important means of transmission, and this concept cannot be abandoned readily.¹⁷⁸ Intact skin of heavily infected patients discharges a few *M. leprae*, but ulcers in the skin may be a source of numerous bacilli. In some studies, bacillary load was the only factor associated with leprosy spread to index case contacts.²⁸⁴ Skin-to-skin contact and fomites containing *M. leprae* could be sources of infection, but this mode has been minimized in recent years in favor of the nasorespiratory route.¹⁴⁷

Studies suggest that the respiratory passages could be an important source of infecting bacilli.⁷³ In one study, 80% of patients with multibacillary leprosy had *M. leprae* DNA in skin washings and 60% had nasal secretions testing positive for *M. leprae* by polymerase chain reaction (PCR). Household contacts were PCR-positive from skin and nasal secretion samples in 17% and 4% of instances, respectively.¹⁴⁷ *M. leprae* organisms ejected in nose blowing remain viable under ambient conditions for 1 week,⁶⁴ and disseminated leprosy develops in immunosuppressed mice after the inhalation of aerosol that contains *M. leprae*.²⁶⁴ Breast tissue and milk from lepromatous patients contain *M. leprae*, and infants may acquire infection from this source.²⁴⁸

Placental transmission of leprosy has been a subject of conjecture for some time, but evidence is growing for a significant influence of leprosy on fetal development and for intrauterine fetal infection. In a study of 156 pregnant leprosy patients in Ethiopia, the placentas were small, and infants had lower birth weight, higher risk for intrauterine growth restriction, and higher infant mortality rates than infants of nonlepromatous mothers.⁸¹ Immunoglobulin A (IgA) and IgM antibodies for *M. leprae* are present in the cord blood of 30% to 50% of infants delivered by mothers with lepromatous leprosy.¹⁹⁷ Evidence is strong for synthesis of fetal antibodies to *M. leprae*. Occasionally, *M. leprae* has been shown in placentas and cord blood and can be detected until 2 years of age.^{137,198,336} Two young children with intrauterine exposure developed leprosy before 18 months of age.⁸⁰

Leprosy in young infants may be a common occurrence in areas of high endemicity.¹¹¹ In a report combining cases from the literature and observations by experienced leprologists, a total of at least 49 infants with leprosy were identified.³¹ In only half of these infants did the mother have a history of leprosy. The youngest infant was 2.5 months old at the time of diagnosis. The fact that many of the mothers never had clinical leprosy suggests that they had transient *M. leprae* bacteremia during gestation. Persistent bacteremia is a common finding in multibacillary disease^{78,171} and is detectable in 15% of paucibacillary patients.¹⁶²

The discoveries of a naturally acquired leprosy-like disease in recently captured wild armadillos in Louisiana,^{332,355} chimpanzees,^{76,114} and Old World monkeys^{204,212} provide reason to consider that leprosy is a zoonosis.³³⁷ Naturally acquired leprosy was found in 16% of nine-banded armadillos in the southeastern United States.³⁰⁶ In all of these species, the histopathologic features resemble those in leprosy in humans, and the bacilli that cause the infection cannot be distinguished from *M. leprae*.^{25,205,211} Leprosy has been transmitted successfully from the mangabey monkey to other mangabey, rhesus, and African green monkeys.^{149,367} No cases of transmission of leprosy to humans from naturally infected mangabey monkeys or chimpanzees have been reported, but this potential exists.^{114,203} Some authorities suggest that insects, including *Aedes aegypti* mosquitoes, may ingest *M. leprae* during a blood meal from lepromatous patients and harbor viable bacteria.¹² The natural transmission of leprosy by insects remains unproven, however.

Epidemiology

The highest incidence rates of leprosy are found in Southeast Asia (including India), which accounted for 72% of new leprosy cases in 2013. The Americas accounted for 15%, followed by Africa (10%), Western Pacific nations (2%), and Eastern Mediterranean countries (1.7%).³⁷⁷ While prevalence has fallen substantially in recent years, this decrease is partially due to decreased treatment durations.²⁷¹ Based on limited whole-population surveys in endemic areas, the total number of active patients may exceed the number reported by the WHO by a significant margin. The stigma of the disease and inefficiency in health care delivery systems contribute to this disparity in statistics.¹³⁹

Between 1994 and 2011, leprosy incidence rates declined from 0.52 to 0.43 per million in the United States; 2323 new cases were reported during this time period. Incidence rates were 14 to 23 times higher in foreign-born persons than in persons born in the United States.²³⁹ Since 2000, an increased number of cases in immigrants from the Marshall Islands and Micronesia has been reported.³⁶⁹ A few indigenous patients regularly come from Louisiana, Texas, other southeastern states, and Hawaii.¹⁷² No instances of secondary transmission from imported cases within the United States have been reported; immigrants with leprosy present no known public health risk to the population of the United

States. The same situation probably is true for other nonendemic countries that receive many immigrants from endemic areas.

In 1871 and 1872, Hansen studied 69 Norwegian families in which several members had leprosy. The prevailing concept of that era was that leprosy was hereditary, but from data gathered on these families, Hansen showed that patients always had contact with another leprosy patient.¹²¹ Hansen reasoned that the spread of leprosy depended on dissemination of this etiologic agent in a susceptible population. The leprosy epidemic in Nauru in the central Pacific area shows how rapidly leprosy can spread in a leprosy-naïve population.¹¹⁵ Leprosy was introduced into this small island in 1912, and by 1924, one-third of the 2500 inhabitants had leprosy.

The prevailing concept has been that an individual becomes infected only after experiencing repeated exposure. This concept now is doubted, and a single exposure may be sufficient in optimal conditions. One report describes leprosy transmission occurring after a single exposure from a patient to a surgeon who practiced in a leprosy nonendemic area.¹ Other reports describe inoculation leprosy after injury with a broken glass bangle¹¹⁰ and after tattooing.³¹⁴ In any patient-contact situation, the number of viable *M. leprae* being shed by the patient and the degree of susceptibility of the contact both may vary. Lymphocyte transformation studies show that occupational contacts of leprosy patients in Ethiopia have the highest rate of sensitization (58%) to *M. leprae*, followed closely by household contacts (47%). Noncontacts living in endemic areas have a lower rate of sensitization, but approximately 29% of the population still is sensitized.¹¹²

Factors facilitating spread of leprosy include multibacillary (versus paucibacillary disease), the nutritional status of a population, and living conditions. The percentage of patients with multibacillary disease (lepromatous leprosy) varies by ethnicity. Multibacillary disease is seen in up to 50% of Asians and only 5% to 10% of Africans. Social factors, such as low educational level, bathing weekly in open water bodies, low frequency of bed linen changes,¹⁶⁴ and food shortages^{94,115,280,316} were associated with leprosy transmission. Nonetheless, convincing evidence that the prevalence of leprosy is unusually high in chronically malnourished populations is lacking, in part because of the collinearity between malnutrition and other markers of socioeconomic deprivation.

Improvements in housing and other living conditions may play a role in the declining prevalence of leprosy. No other factor satisfactorily explains the virtual disappearance of leprosy from northern Europe after the Middle Ages and from Scandinavia in the 20th century, long before any effective chemotherapy was available. If the disease is predominantly airborne, the construction of dwellings that provide less confined sleeping quarters in this era could have contributed to reduced incidence rates in these regions. Consistent with this concept is the inadequate housing that prevails in all geographic areas in which leprosy is common today. Another explanation for declining leprosy cases in Europe after the 15th century was that the rudimentary infection control and isolation of lepromatous patients may have had an impact.³⁰⁷

The presumed increased susceptibility of children is difficult to establish and may depend more on exposure to contagious patients and genetic predisposition than on other factors. In most populations studied, only 5% to 10% of individuals are susceptible to leprosy. The proportion of children among all detected patients is 20% to 30%.^{106,241} Lara,¹⁷⁴ in a study of 2000 Filipino children who lived in a leprosarium in the prechemotherapy era, noted that leprosy developed in 470 (23%). In 75%, the lesions healed spontaneously; active, persistent disease developed in approximately 6% of heavily exposed children. In adults, leprosy occurs more commonly in men than in women (2:1 to 3:1). In children, the sex ratio is approximately 1:1.

Genetic factors likely influence the susceptibility of some individuals to leprosy and the form of disease that develops.^{95,99,100,311} Several polymorphisms have been associated with leprosy susceptibility. These include a mannose gene, interleukin (IL)-10, and tumor necrosis factor (TNF) receptor mutations.^{286,308} TNF promoter mutations are particularly associated with development of lepromatous or multibacillary leprosy.²⁷⁶ Other mutations identified include those on chromosome 6 near the Parkinson disease gene *PARK2* and *PACRG* genes,^{213,214} vitamin D receptor gene,⁹⁹ interferon (IFN)- γ receptor-1 gene promoter (*IFNGR1*) polymorphisms,³⁴⁴ and the nucleotide-binding

oligomerization domain-containing protein 2 (NOD2)-mediated signaling pathway, which helps mediate innate immune responses.³⁸² Certain human leukocyte antigens (*HLA-DR*) seem to be associated with specific forms of leprosy. *HLA-DR2* and *HLA-DR3* alleles are associated with tuberculoid disease, and *HLA-DQ1* is associated with lepromatous disease.⁵⁵ *HLA-DR* antigens may influence the presentation of antigens of *M. leprae* to T cells and may affect the immune response to leprosy.²⁴⁵

Toll-like receptors (TLRs), molecules present on the surface of innate or native immune cells, mediate cytokine production on encountering a foreign invader, including mycobacteria, and ultimately may influence the pattern of specific immunity.^{193,275} Lepromatous leprosy occurs more commonly in patients with a mutation in the TLR-2, associated with altered production of IL-10 and IL-12, underscoring the role early cytokine responses against *M. leprae* may play.^{152–154} Another SNP, this one in the TLR-1 transmembrane domain, was associated with diminished nuclear factor- κ B (NF κ -B) activity and found to have reduced cytokine responses to *M. leprae*.^{215,368} In African patients, polymorphisms in the *NRAMP1* gene, a gene also associated with cellular immunity to *M. tuberculosis*, are associated with lepromatous leprosy,¹⁹⁶ as shown in the Mitsuda reaction.^{6,260}

Pathogenesis and Pathology

M. leprae causes disease by its ability to survive and multiply in macrophages (Fig. 98.1).²⁹⁴ If macrophages of the host digest the bacilli early, disease is undetectable or the patient has only minimal lesions. If the macrophages are totally incapable of destroying the organisms, widely disseminated lepromatous leprosy follows. Survival of *M. leprae* in macrophages depends on the immune response of the patient; knowledge of immunity to *M. leprae* is necessary for understanding the mechanism of pathologic changes in leprosy.

Immunity

The immunopathogenesis of leprosy can be understood by examining the polar nature of the condition, whereby tuberculoid disease is characterized by one or several well-demarcated lesions, borderline disease manifests with a modest number of medium-sized lesions, and lepromatous disease manifests with widespread poorly demarcated lesions (Table 98.1). Each type is associated with a different immunologic profile, especially within the lesions.

The ability of an individual to resist *M. leprae* is assessed readily by the induration provoked by an intradermal injection of a suspension of killed *M. leprae* prepared from lepromatous tissue from armadillos.²⁰⁶ The reagent is known as *lepromin*, and the response is known as the *lepromin reaction*.²¹⁷ This reaction has two components: an early response at 48 hours (Fernandez reaction) and a late response at 3 to 4 weeks

FIG. 98.1 Electron micrograph of a portion of a globus of *M. leprae* within a histiocyte in a leproma in the skin. Cross sections of (A) well-preserved and (B) degenerated bacilli are presented (×45,000). (Courtesy Dr. S.C. Chang.)

TABLE 98.1 Criteria for Classification of Leprosy

Group	Clinical Features	Histologic Features	Lepromin Reaction (Mitsuda)	Bacillary Density
Tuberculoid	Single or few anesthetic macules or plaques Borders well defined Peripheral nerve involvement common	Epithelioid-lymphocyte granulomas, with or without giant cells, in skin and nerves No subepidermal clear zone Bacilli in nerves, but rare	Strongly positive	Rare
Borderline tuberculoid	Lesions similar to those of tuberculoid, but more numerous Borders of lesions less distinct Satellite lesions sometimes present around larger lesions Peripheral nerve involvement common	Granulomas similar to those in tuberculoid Nerves are infiltrated Bacilli frequently found in nerves	Positive	Scanty
Borderline	More lesions than in borderline tuberculoid Borders more vague Satellite lesions often seen Peripheral nerve involvement common	Epithelioid cells and histiocytic infiltrations focalized by lymphocytes Nerves show increased cellularity Bacilli readily found in nerves	Negative or weakly positive	Moderate
Borderline lepromatous	Lesions are numerous and similar to those of borderline Some nerve damage	Histiocytic infiltrations show a tendency to evolve toward epithelioid cells and foamy cells Lymphocytes present Nerves have less cellular infiltration Bacilli plentiful in nerves	Negative	Heavy
Lepromatous	Multiple, nonanesthetic, macular or papular, symmetrically distributed lesions No neural lesions until late Late complications of madarosis, leonine facies, testicular damage	Foamy histiocytes containing large numbers of bacilli Few or no lymphocytes Subepidermal clear zone Numerous bacilli in nerves and perineurium without significant intraneural cellular infiltration	Negative	Very heavy
Indeterminate	Vaguely defined hypopigmented or erythematous macule	Often indistinguishable from mild nonspecific dermatitis Lymphocytes and histiocytes around skin appendages and nerves	Weakly positive or negative	Negative or scanty

(Mitsuda reaction). The Mitsuda reaction is the most consistent and is used by clinicians as an aid in classifying the clinical forms of leprosy.

Mitsuda reactions are strongly positive (>5 mm in diameter) in tuberculoid patients, weak or negative (0 to 2 mm) in lepromatous patients, and intermediate (3 to 5 mm) in patients with borderline disease. The reactions are a direct measure of delayed hypersensitivity or cell-mediated immunity to *M. leprae* antigens; lepromatous patients are anergic to *M. leprae*, akin to anergy to the tuberculin skin test (TST) seen in children with tuberculous meningitis or miliary tuberculosis. Also similar to the TST, the lepromin reaction has no value in establishing the diagnosis because a high percentage of any population is Mitsuda positive. One study evaluated the Mitsuda response in Indian children residing in leprosy-endemic regions. Percent positivity was higher in low-endemic regions than high-endemic areas (93% and 88%, respectively), indicating that the Mitsuda response is independent of *M. leprae* exposure.³⁰³ Nonspecific factors participate in host defense against *M. leprae*. Complement promotes phagocytosis of leprosy bacilli.²⁹⁰ Although the precise mechanisms of specific immunity remain elusive, abundant experimental evidence indicates that in a lepromatous leprosy (multibacillary) patient, cell-mediated immunity to *M. leprae* is markedly suppressed.³⁵ The degree of suppression is gradually less pronounced in clinical forms of disease that are progressively nearer tuberculoid (paucibacillary) leprosy.³⁵⁶ Patients with multibacillary forms of leprosy are found to have decreases in the total numbers of circulating T lymphocytes,⁸⁴ despite normal T-cell subsets,²⁶¹ or decreased lymphocyte function.²²⁸ CD4⁺ T lymphocytes predominate in paucibacillary disease and produce IFN- γ ,^{285,380} whereas CD8⁺ lymphocytes predominate for multibacillary disease and produce IL-4.²⁸⁵ This immunologic dichotomy between tuberculoid and lepromatous lesions is consistent with the paradigm that robust cell-mediated immunity limits disease progression and that humoral immunity has little or no effect.

Macrophages of lepromatous patients are thought to have the capacity to kill, digest, and clear *M. leprae* if they are activated.¹³⁰ Patients with

lepromatous leprosy fail to produce IL-2, but IL-2 restores the proliferation of lymphocytes in response to specific antigens.¹²³ Defective IFN- γ is produced by lymphocytes from lepromatous patients on stimulation by *M. leprae* antigens.²³⁸ IL-2-bearing lymphocytes are reduced markedly in lepromatous infiltrations in tissues.²¹⁹ These combine to result in macrophages not being activated. The injection of IFN- γ or recombinant IL-2 into the skin of lepromatous patients causes a local influx of CD4⁺ T cells along with the formation of epithelioid and giant cells and a reduction in bacillary load.^{156,346} Therapy with IL-2 or IFN- γ induces the secretion of TNF- α ; however, the activity of this toxic molecule may be inhibited by thalidomide or pentoxifylline.^{155,328} TNF- α is associated with macrophage infiltration of peripheral nerves in reversal reactions.¹⁶⁵ Whether the increasing use of TNF- α antagonists would be associated with the development of leprosy from latent infections or perhaps be useful in the management of leprosy reactions remains unclear.^{88,295}

Immunoglobulin production (i.e., IgG, IgA, and IgM) usually is elevated only slightly in tuberculoid patients but is elevated markedly in lepromatous patients, consistent with the predominant T_H1 versus T_H2 responses.³⁶ The total number of B lymphocytes is increased in the blood of lepromatous patients, as is the circulating antibody to mycobacterial antigens.²³⁴

Histopathology

Biopsy specimens from well-defined lesions of leprosy should be taken from the active border (not the center of the lesion) and fixed in buffered 10% formalin or other suitable fixative. The Fite-Faraco staining method conventionally is used because the Ziehl-Neelsen (ZN) stain does not show *M. leprae* optimally in tissue sections. However, Fite-Faraco staining is time-consuming, can result in observer fatigue (particularly in paucibacillary cases), and has sensitivities of 45% to 60%. In contrast, ZN stains²⁶⁵ and rhodamine-auramine fluorescent stains²³⁵ have sensitivities of 50% and 70%, respectively. Combining Fite-Faraco staining with PCR can provide more rapid diagnoses than other modalities used in

isolation.²⁶⁵ A histopathologic diagnosis of leprosy must not be made unless the evidence is convincing. In nonendemic regions, providing additional history to the pathologist can allow for clinicopathologic correlation.²⁷³

Indeterminate leprosy. Indeterminate leprosy (Fig. 98.2) is characterized by mild chronic inflammation (Fig. 98.3). If leprosy is suspected, all

FIG. 98.2 Hypopigmented macule of indeterminate leprosy on the anterior surface of the leg of an Indian girl.

FIG. 98.3 (A) Indeterminate leprosy showing only mild infiltrations along neurovascular channels in the deep dermis (hematoxylin and eosin stain). (B) Only a single acid-fast bacillus was found in one deep dermal nerve (arrow) after a search of multiple sections (Fite-Faraco stain).

nerves in the dermis and subcutaneous tissue in numerous sections of the biopsy specimen must be searched for acid-fast bacilli, even if no inflammatory changes within the nerves are present. Sometimes acid-fast bacilli are more common in the arrector pili muscles or subepidermal zone,²⁶⁷ but are rarely seen in normal-appearing skin.³² Angiogenesis is not common in indeterminate leprosy skin lesions, in contrast to other forms.²¹ A histopathologic diagnosis requires demonstration of acid-fast bacilli. PCR is less sensitive in paucibacillary forms, such as indeterminate leprosy, when compared to multibacillary forms. However, given the diagnostic difficulties for indeterminate leprosy, PCR can greatly augment diagnostic yield compared to slit-skin smears for acid-fast organisms.¹³

Tuberculoid leprosy. Tuberculoid leprosy (Fig. 98.4) is characterized by granulomata in the dermis, epidermis, and subcutaneous tissues (Fig. 98.5A). Damage to nerves is a distinctive feature; in advanced lesions, all cutaneous nerves may be damaged beyond recognition (see Fig. 98.5B). This nerve damage is best visualized by S-100 immunostaining, which reveals a neural pattern of Schwann cells. Bacilli rarely are found, and often many sections must be searched to locate a single bacillus. The bacilli usually are within remnants of dermal nerves but sometimes are located just beneath the epidermis. When major nerve trunks are involved, they contain typical tuberculoid infiltrates that eventually may replace the entire nerve. Occasionally, caseous “abscesses” are present in large nerves; these are rare in children.

Borderline leprosy. Borderline leprosy represents a broad spectrum of clinical (Fig. 98.6) and histopathologic variations (see Table 98.1). In the borderline-tuberculoid variety, nerves usually are damaged less and are identifiable more readily than in tuberculoid leprosy. *M. leprae* often remain rare but are seen more readily than in tuberculoid leprosy in nerves (Fig. 98.7) or in the subdermal zone. Acid-fast bacilli can be seen in arrector pili muscle in normal-appearing skin in 17% to 25% of cases of borderline leprosy.³² Some histopathologists do not recognize borderline leprosy as an entity because there is usually a suggestion that the lesion is on either the borderline-tuberculoid or the borderline-lepromatous side of the spectrum of the disease.¹⁴⁶ Borderline-lepromatous lesions are characterized by granulomas, easily identified nerves with perineurium infiltration, and readily visualized bacilli.

Lepromatous leprosy. Prelepromatous lesions show only a mild proliferation of macrophages around vessels, nerves, and appendages. Acid-fast bacilli are few and often difficult to show. As the disease progresses, the bacilli-laden macrophage (Virchow cell or lepra cell) becomes the predominant inflammatory cell (Fig. 98.8). In early lesions, they tend to accumulate around vessels, nerves, and appendages, but they eventually may replace the entire dermis (Fig. 98.9A). As the macrophages age, they become vacuolated (foamy), largely from their lipid content. In developing lesions, the intracellular bacilli are arranged in small bundles (see Fig. 98.9B); in advanced lesions, dense masses of bacilli termed *globi* may replace nearly the entire cytoplasm of the

FIG. 98.4 Tuberculoid leprosy in a 12-year-old Congolese boy. This was the only lesion; it has a well-defined papulated border with central healing.

FIG. 98.5 (A) Tuberculoid leprosy with a dense granulomatous infiltration that invades the epidermis. Granulomata contain epithelioid cells, Langhans giant cells, and lymphocytes (hematoxylin and eosin stain). (B) High magnification of a nerve bundle in the subcutaneous tissue of section in (A). Granulomata have nearly completely destroyed the nerves. Remnants of nerves contained rare acid-fast bacilli (hematoxylin and eosin stain).

macrophage. Many bacilli are found in the dermal nerves and frequently in endothelial cells, walls of blood vessels, arrector pili muscles, and epithelial cells of hair follicles.²²⁶ In one case series, acid-fast bacilli were found in arrector pili muscle in normal-appearing skin in more than 50% of patients with lepromatous leprosy,³² with implications for both disease extent and recurrence risk. Lymphocytes are scant. Large nerve trunks may show typical lepromatous infiltrations.

Occasionally, in patients with lepromatous leprosy, elevated firm nodules form in the skin, especially in relapsing disease. Because of the characteristic histologic pattern of these lesions, in which the spindle-shaped histiocytes resemble fibrocytes, this form is called *histoid leprosy*.^{297,351} Lepromatous leprosy is disseminated widely, and lepromatous infiltrations frequently are found in the upper respiratory tract, as far down as the larynx, and in the eyes and testes. In adults, the testes sometimes are densely infiltrated, with subsequent development of sterility and gynecomastia, but these complications are rare findings in children. Lymph nodes often are infiltrated by bacilli-laden macrophages, especially in the medulla and paracortical areas.

FIG. 98.6 Borderline lepromatous leprosy in a Filipino. There are many plaques, some with well-defined borders and others vaguely defined. The erythematous plaques indicate that the patient is undergoing an upgrading reversal reaction (type 1).

FIG. 98.7 Electron micrograph of a portion of a damaged dermal nerve in borderline leprosy. A nonmyelinated axon (A) is surrounded by a Schwann cell (SC) that contains a single *M. leprae* bacillus (ML) (x60,000). (Courtesy Dr. S.C. Chang.)

FIG. 98.9 (A) Advanced lepromatous leprosy showing replacement of dermis by foamy histiocytes and very few lymphocytes. Note thin subepidermal clear zone (hematoxylin and eosin stain). (B) Higher magnification of same biopsy specimen showing clumps of *M. leprae* (globi) in histiocytes in a leproma in the skin (Fite-Faraco stain).

Clinical Manifestations

The incubation period varies (usually 2 to 5 years), and no prodromal manifestations are well established. Some experienced clinicians working in areas of high prevalence recognize early signs of nerve involvement (i.e., localized paresthesia, itching, or numbness) before any visible lesions develop. Paucibacillary leprosy is defined as having one to five skin lesions, and includes all smear-negative cases. Multibacillary leprosy includes more than five skin lesions and includes all smear-positive cases. The extreme forms of leprosy include tuberculoid (paucibacillary disease) and lepromatous (multibacillary) leprosy, with other forms falling between these extremes. Differentiation of paucibacillary from multibacillary disease is important for selection of the number of empirical medications started, duration of therapy, and risk for relapse and sequelae.

After the incubation period, various lesions appear. The nature of the lesions depends on the immune response of the patient to *M. leprae*. So far, no variations in strain have been found to explain the leprosy phenotype.^{363,364} Most clinicians today follow the classification scheme outlined by Ridley and Jopling (see Table 98.1).²⁶⁸ This classification system is based on clinical features, histopathologic findings, bacterial load, and reaction to the Mitsuda test. On one extreme is tuberculoid leprosy, characterized by a robust cell-mediated immune response and paucibacillary disease. On the other extreme is lepromatous leprosy, a multibacillary form characterized by more of a humoral immune response. Classification is important because it aids in establishing the prognosis and treatment program for the patient. The distribution of leprosy types varies geographically. In Latin America, lepromatous leprosy was the most common,³⁴² whereas borderline leprosy was more common in India.²⁴⁰

Virtually all patients with leprosy have peripheral neuropathy if cutaneous sensory changes are included, and approximately 25% have significant deformity. In experimental studies, the pathogenesis of peripheral neuritis in leprosy involves bacillation of the endothelial cells of epineural and perineural blood vessels and lymphatics.^{293,294,296}

Ocular complications in leprosy are well known, especially in lepromatous leprosy. These lesions can include corneal scarring; conjunctivitis; and eyelash abnormalities, including ectropion (eversion of lid margin from globe), lagophthalmos (inability to close eyelids completely), madarosis (loss of eyelashes), and trichiasis (eyelashes growing back toward globe).^{56,60,61,85,128} All patients with leprosy should be evaluated by an ophthalmologist at diagnosis and periodically thereafter, especially during any reactional episodes. Reactional episodes can involve ocular hypotension, punctate keratitis, and uveitis.⁶³

Indeterminate Leprosy

An indeterminate lesion is the first manifestation of leprosy in most patients and may heal spontaneously, remain unchanged for months or years, or gradually progress toward tuberculoid or lepromatous disease. Patients with indeterminate leprosy have a single or a few macules in the skin (see Fig. 98.2). The macule is defined poorly and is mildly hypopigmented in deeper pigmented skin and slightly erythematous in lighter skin. Skin texture, presence of body hair over the lesion, sensation, and sweating within early macules are normal or only slightly altered. Peripheral nerves are normal, and skin smears from lesions rarely contain bacilli. The definitive diagnosis can be made only by finding acid-fast bacilli in histopathologic sections.

Tuberculoid Leprosy

Tuberculoid leprosy is the paucibacillary extreme of leprosy. Patients with tuberculoid leprosy have a single or several asymmetrically distributed hypopigmented skin lesions (see Fig. 98.4). Tuberculoid lesions arise de novo or evolve from indeterminate macules. The lesion may be macular or infiltrated, but the borders always are sharply demarcated, usually elevated from the surrounding normal skin, and frequently are finely papulated. Lesions range in size from less than 1 cm to large enough to cover entire regions, such as the thigh or buttock. Many tuberculoid lesions heal spontaneously. In large, active lesions, the centers often are healed and repigmented, although somewhat atrophic. The lesions often are hairless, hypohidrotic, and anesthetic. Sensation is lost in a specific order: first is loss of thermal sensation, then tactile, and loss of pain sensation is seen in more advanced disease. On the face, because of its rich innervation, the detection of hypoesthesia in early lesions requires discriminating tests. Conversely, clinicians may mistakenly diagnose leprosy in areas of the body that normally are hypoesthetic (e.g., over the elbows or knees). Despite hypoesthesia, deep pain on percussion of lesions over bone in tuberculoid leprosy, termed the *tap sign*, has been described, with a sensitivity of 67% and specificity of 100%.¹⁶⁹

Involvement of peripheral nerves commonly occurs in tuberculoid leprosy (Fig. 98.10), and cutaneous nerves often can be palpated adjacent to or within lesions. The regional nerve trunks most commonly enlarged are the ulnar from the olecranon groove to midarm, lateral popliteal just distal to the head of the fibula, and posterior tibial in the medial aspect of the ankle. Enlarged or tender nerves anywhere should alert the clinician to the possibility of leprosy. Any readily palpable cutaneous nerve probably is enlarged, but evaluating the size of nerve trunks requires experience because of the wide range in normal size. Slit-skin smears are usually negative for acid-fast organisms.

Borderline Leprosy

Borderline leprosy, sometimes called *dimorphous* or *intermediate leprosy*, has features of the lepromatous and tuberculoid forms and represents a continuous spectrum of disease ranging from near-tuberculoid to near-lepromatous. It is an unstable form of leprosy and may evolve gradually toward tuberculous leprosy by undergoing reversal reactions or be downgraded toward lepromatous leprosy. Table 98.1 describes the three major subgroups of borderline leprosy: borderline-tuberculoid, borderline, and borderline-lepromatous.

In borderline-tuberculoid leprosy, the number of lesions (>10) usually is greater than in tuberculoid leprosy, and the borders of each lesion,

FIG. 98.10 Enlargement of the great auricular nerve in an adolescent Congolese boy. A large macule of tuberculoid leprosy over the angle of the mandible is now nearly inactive and barely visible.

macule, or plaque are defined less sharply than in tuberculoid leprosy. Ulceration of cutaneous lesions may occur. Small satellite lesions may develop around larger macules or plaques or extend as finger-like projections from larger lesions. Acid-fast smears are variably positive.

Borderline leprosy is characterized by hypochromic plaques that are well defined and have apparent central sparing of the skin. Skin findings may include papules, plaques, macules, or nodules and the lesions are sometimes described as having a “Swiss cheese” appearance.³²⁹ Acid-fast smears often are strongly positive.

Borderline-lepromatous leprosy often manifests with widespread nodular infiltrations or plaques of varying size (see Fig. 98.6). The lesions are hypochromic and symmetrically distributed. Over time, the lesion borders become irregular as normal skin is invaded. Nontender peripheral nerve involvement is common. Acid-fast smears are strongly positive.

Damage to nerves and the resulting deformity develop early and often are widespread. Most patients who are disabled due to neuropathy are within the borderline spectrum of leprosy. It is often these neuropathic changes (e.g., sensory changes that lead to damaged hands or feet or a muscular weakness such as footdrop) that bring the patient to medical attention. Severe damage to nerves occurs infrequently in young children, but can be disastrous. Prevention of this complication is an important goal of leprosy detection programs and of treatment in every patient with leprosy.

Lepromatous Leprosy

Lepromatous leprosy is the classic multibacillary disease extreme. Here, peripheral blood smears can be positive for acid-fast bacilli (up to 80% in one study),⁷⁸ and the disease disseminates widely, often before striking cutaneous manifestations develop. In its earliest form, lepromatous leprosy manifests as “juvenile leprosy,” a clinical entity delineated from observations of large numbers of children in homes for children of patients with leprosy in India.²²⁵ This form, also called *prelepromatous leprosy*, is difficult to detect and frequently goes unrecognized until a more advanced stage develops. Skin texture may be altered slightly, but the vague macules with indistinct borders are detected only under appropriate lighting, preferably daylight. No changes in sensation or sweating occur in the macules, and frequently acid-fast bacilli are not detectable in skin smears. Histopathologic sections may reveal a few bacilli to confirm the diagnosis; however, if leprosy is suspected, the patient should be monitored until an explanation for the mild skin changes is found. If leprosy is present and not detected and treated, advanced forms of lepromatous leprosy develop in many of these patients (Fig. 98.11).

FIG. 98.11 Progression of lepromatous leprosy in a Hawaiian boy. The photograph at *left* was taken in 1931, when the patient was 13 years old; the photograph at *right* was taken 2 years later. No effective chemotherapy was available in that era.

The hypopigmented or slightly erythematous macules of early lepromatous leprosy, similar to those of juvenile leprosy, are missed easily because they are vague and have slight, if any, sensory changes. These macules usually are small but gradually may coalesce and cover large areas of skin, even nearly the entire body. Clinical diagnosis often is missed, and over the course of a few years, advanced lepromatous leprosy develops. If skin smears or biopsy specimens are taken in the macular stage, diagnosis is virtually ensured. If the disease is not diagnosed and treated in the macular stage, infiltration of the skin increases gradually and nodules may develop. The skin is infiltrated most heavily in the cooler portions of the body, notably the ears (pinnae) and face. By this time, nerves usually are enlarged, with early signs of sensory loss in the hands and feet. Eyebrows are thinned and eventually lost, beginning at the lateral edges. Loss of eyelashes (madarosis) often is seen. These well-known advanced changes of lepromatous leprosy are not common findings in young children.

Involvement outside the integument is common in patients with lepromatous leprosy. This includes involvement of the upper respiratory tract, characterized by mucopurulent nasal drainage and epistaxis due to involvement of the palate, larynx, and nasal bones. Destruction of eyelashes and eyebrows can result in corneal trauma, including ulceration, perforation, and infection. Iritis, uveitis, and glaucoma are late findings. Dissemination to the reticuloendothelial system, adrenals, and testes can be seen during hematogenous spread. Acid-fast smears are strongly positive.³²⁹

Histoid leprosy, one variant of multibacillary leprosy, often is classified with lepromatous leprosy. Here, firm, dome-shaped nodular or papular lesions show constriction around the base. They are more commonly found in the axial skeleton.²⁹⁷ This form of leprosy is more common among patients whose isolates are resistant to dapsone.³⁵¹

Patients of Latin American ancestry, especially patients from Mexico and Costa Rica, may contract the highly anergic diffuse form of lepromatous leprosy called *Lucio-Latapi leprosy*. The disease may be so diffuse that it is not recognized until sensory changes appear in the hands and feet, and the eyebrows and other body hair begin to disappear. The skin appears shiny and moist, resulting in a healthy appearance to the skin that led this condition to be called *lepra bonita* (pretty leprosy). In advanced forms of Lucio leprosy, a necrotizing panvasculitis in the skin is present, with the production of dermal infarcts and irregular ulcers (Lucio phenomenon).^{175,262} Lucio leprosy has been reported in children 7 years old.²⁸⁹

Neuritic Leprosy

Neuritic leprosy, a relatively rare form of the disease, manifests as motor or sensory impairment in one or multiple nerves in the absence of cutaneous changes. Symptoms include anesthesia, paresis, and wasting of muscles in the affected area. Nerve trunks frequently are painful, enlarged, and tender. Leprosy must be suspected in patients with any peripheral neuritis that has these features. Chronic neuropathy and nerve enlargement often persist for years after the patient has completed chemotherapy for leprosy.¹²⁷ Large leprotic nerve abscesses are rare

occurrences but are exquisitely painful and may require surgical intervention for drainage.³⁰⁰ Most clinicians prefer to treat such lesions with corticosteroids. From a classification standpoint, patients with one to two nerves are deemed to have paucibacillary disease and those with more than two nerves involved are considered to have multibacillary disease. The diagnosis is difficult and may require PCR, as acid-fast smears usually are negative.

Leprosy and Acquired Immunodeficiency Syndrome

Given the history of acquired immunodeficiency syndrome (AIDS) altering the epidemiology and undermining control efforts for the other mycobacterial species with human-to-human transmission, *M. tuberculosis*, concern exists that a similar phenomenon might be seen with *M. leprae*.³³⁵ The degree to which HIV impacts leprosy incidence is unclear. Some studies in sub-Saharan Africa have shown that HIV seroprevalence was two to five times higher in leprosy patients than controls.^{28,194} Perhaps the positivity of some of these patients with leprosy can be explained by cross-reactivity between antibodies to HIV-1 and the lipoarabinomannan of *M. leprae*.¹⁶⁰

However, most studies have shown that HIV seroprevalence among leprosy patients is no higher than the general population and that clinical manifestations are similar in coinfecting patients and patients with leprosy alone.^{143,163,170,222,299,335} Other prospective studies show that HIV infection may not be a risk factor for acquisition of leprosy in some populations.^{163,299} However, HIV-infected patients seem to be more at risk for leprosy complications than HIV-seronegative patients. The incidence of reversal reactions (type 1, described later) and neuritis is increased in multibacillary patients coinfecting with HIV.³⁸ These reactions, similar to immune reconstitution inflammatory syndrome (IRIS), have been described for both forms of IRIS.³³⁵ Paradoxical IRIS, in which worsening of leprosy lesions is seen while on both appropriate leprosy and antiretroviral therapy, has been described with borderline leprosy; reactions often are local, not systemic.¹⁶ Unmasking IRIS, in which leprosy symptoms develop anew in a person on antiretroviral therapy, has been described in a patient with borderline tuberculoid leprosy.¹⁷⁷

Reactions

The course of leprosy, treated or untreated, often is interrupted by acute episodes known as reactions, which fall into two general categories: reversal reactions (or type 1) and erythema nodosum leprosum (or type 2).⁷²

Reversal Reactions

Reversal reactions complicate borderline leprosy and represent delayed hypersensitivity reactions, with an upgrading of cell-mediated immunity toward tuberculoid leprosy. Lesions become erythematous and edematous, and neuritis is common (Fig. 98.12). Risk factors for reversal reactions include being lepromin positive and having PGL-1 IgM antibodies.²⁷⁰ Proliferation of sensitized T lymphocytes initiates reversal reactions and amplifies the inflammatory response by releasing lymphokines and activating macrophages.²⁷⁴ Effective chemotherapy for paucibacillary and multibacillary patients may activate cell-mediated immunity and provoke clinical or subclinical reversal reactions (similar to IRIS). In severe reactions, necrosis may occur, almost always in nerves. Increased levels of TNF- α may partially explain this necrosis.²³ Cyclooxygenase-2 (COX-2) levels are elevated in nerves and blood vessels during reversal reactions, a finding that explains why nonsteroidal antiinflammatory drugs, including selective COX-2 inhibitors, often improve the condition.²⁴⁹ Patients experiencing such reactions must be observed closely so that sensory loss and deformities are minimized.

Differentiating reversal reactions from relapsing lesions frequently is difficult and requires careful correlation of clinical and histopathologic findings. This correlation is becoming increasingly important in endemic areas, where shorter term chemotherapeutic regimens of fixed duration are used.^{101,200} The following criteria for differentiating relapses and reversal reactions are suggested: a relapse involves an increased number of lesions; positive skin smears for acid-fast bacilli (for patients with a borderline area of leprosy and borderline-lepromatous leprosy); tissue reaction inconsistent with a reversal reaction; and a favorable response to chemotherapy. A reversal reaction involves an exacerbation of existing

FIG. 98.12 Reversal reaction (type 1) in an 8-year-old Congolese boy with borderline-tuberculoid leprosy. The left side of his face is swollen and displays mild palsy from facial nerve damage. The patient responded rapidly to oral steroid therapy.

lesions; skin smears negative for acid-fast bacilli; tissue reaction consistent with a reversal reaction; and a rapid response to antiinflammatory drugs.

Erythema Nodosum Leprosum

Formerly, erythema nodosum leprosum (ENL) developed in approximately 50% of lepromatous leprosy patients after they had undergone a few months of chemotherapy; however, with the addition of clofazimine to the standard therapeutic regimen, the frequency is much lower.⁹¹ One systematic review found that ENL developed in 1.2% of all leprosy cases, but was higher in patients with multibacillary disease (including 15% of patients with lepromatous leprosy).³⁴⁹ Tender erythematous subcutaneous nodules develop rapidly (Fig. 98.13) and may ulcerate; the nodules often are accompanied by fever, synovitis, and iridocyclitis.²⁵² Erythema nodosum leprosum resembles the Arthus reaction and is thought to result from immune complex formation.¹⁰⁷ Erythema nodosum leprosum is associated with serum TNF- α elevation^{23,288} and intralesional increases in helper T lymphocytes.²¹⁸

A neutrophilic vasculitis is the hallmark of the tissue reaction. Demonstration of serum amyloid A and C-reactive protein may aid in establishing the diagnosis in patients without neutrophilic infiltration.¹³³ Glomerulonephritis sometimes complicates this condition; secondary amyloidosis is a late sequela of repeated reactions and may be a consequence of the neutrophilic leukocytosis.¹⁹⁰ More recent studies indicate that renal involvement is less severe and more reversible in the modern era, likely due to the use of multidrug therapy and more effective treatment of reversal reactions.²⁵³ Occasional patients may have mixed reversal (upgrading) reactions and erythema nodosum leprosum. These patients usually have leprosy in the borderline-lepromatous area of the spectrum.

Diagnosis and Differential Diagnosis

The cardinal signs of leprosy are hypoesthetic lesions of the skin, enlarged peripheral nerve or nerves, and acid-fast bacilli in skin smears. In the

FIG. 98.13 Erythema nodosum leprosum in an adolescent Filipino girl with lepromatous leprosy.

absence of another clear explanation, any one of these signs strongly suggests leprosy.

An experienced observer can establish a clinical diagnosis in most patients, except those with early leprosy, with a high degree of accuracy. Because leprosy is considered one of the “great imitators,”³⁵⁴ however, histopathologic evaluation is strongly recommended to supplement and confirm the clinical diagnosis. Patients with leprosy may be found in almost any geographic area, an awareness of which would minimize missed and delayed diagnoses, especially in areas of low prevalence. In the United States, the usual delay in establishing the diagnosis after the patient’s first visit to a physician for symptoms related to leprosy is approximately 1.5 to 2 years. This delay often significantly worsens the prognosis.

History is important. Contact with patients with leprosy or residence in an endemic area raises suspicion of leprosy in a patient with a chronic lesion of the skin. Sensory loss or unexplained damage to hands or feet suggests damage to nerve trunks. Sometimes, a footdrop or clawhand brings the patient to a physician. Occasionally, patients with lepromatous leprosy consult an otolaryngologist first because of a chronic stuffy nose.

Clinicians must evaluate sensory changes in a lesion using the precautions already mentioned. The modalities usually tested are light touch with the use of a few fibers of cotton or calibrated nylon threads and heat and cold discrimination with the use of warm and cold water in test tubes. Much patience and repeated testing often are necessary in evaluating young children. Spontaneous sweating can be observed directly, or induced sweating can be evaluated. Hair may be completely preserved in early lesions but lost in advanced lesions. The main nerve trunks must be palpated for tenderness and enlargement. Skin in the area of discrete lesions also must be palpated gently to detect enlargement of cutaneous nerves. Globally, leprosy is the most common cause of peripheral neuropathy and must be considered in any patient with peripheral neuropathy.²⁸¹

The histamine test can assist in the diagnosis of indeterminate leprosy in light-skinned patients. This test consists of applying one drop of histamine (1/1000 dilution) within and around hypochromic lesions. The test is positive if, after 1 to 2 minutes, a triphasic (response of Lewis) is observed. This response consists of a line of erythema followed by a wheal and flare response. This triphasic response is *not* seen with leprosy, but is seen for other causes of hypochromic skin.³²⁹

Obtaining and examining smears for acid-fast bacilli is an important diagnostic procedure and should be controlled carefully by experienced laboratories. Briefly, smears are made from the edge of discrete macules or plaques, nodules, ear lobes, and nasal mucosa. Fine needle aspirate has a sensitivity over 90%.¹⁹⁵ Slit-skin smears are made by squeezing and holding a fold of skin between the thumb and forefinger to avoid getting blood in the smear and by making a short, shallow slit in the skin with a razor blade or scalpel. The instrument is turned at a right angle to the slit, and the edges of the incision are scraped. The cells and fluid thus obtained are spread on a slide, heat fixed, and stained by the Ziehl-Neelsen method.³⁴⁵ Evaluation of smears should not be

done by researchers unfamiliar with their interpretation. An occasional acid-fast bacillus may be a harmless contaminant in the staining reagents. DNA probes specific for *M. leprae* are available and are useful in identifying leprosy bacilli in tissue or nasal secretions.^{73,365}

The lepromin reaction is useless for the diagnosis of leprosy.³⁴ Currently available skin tests with soluble *M. leprae* antigens are unreliable.¹²⁰ Enzyme-linked immunosorbent assays and gelatin particle agglutination tests for antibodies to the PGL-1 of *M. leprae* are available.^{45,113,138} Although specificity for *M. leprae* is high, these tests are insensitive (50%) for patients with paucibacillary leprosy. Other serologic tests for antibodies to *M. leprae*-specific epitopes on protein moieties of the bacillus are being evaluated.²⁴⁷ PGL-1 antigen is detectable in the serum and urine of most multibacillary patients.^{242,381} PGL-1 antibodies also have been used for early leprosy diagnosis in household contacts.¹⁷

Interferon gamma release assays (IGRAs) evaluating *M. leprae*-specific cell-mediated immunity have more recently been developed.²⁴⁴ The optimal combination of antigens remains unclear, and these assays likely will not distinguish among healthy endemic controls and patients.

Reliance on DNA probes and PCR technology may prove useful in establishing the diagnosis of leprosy in tissue sections, skin smears, and nasal smears.^{73,327,363,365} Whole-blood PCR is more sensitive for patients with multibacillary than paucibacillary disease (95% versus 70%), and can also be positive in asymptomatic household contacts.³⁶² Because these methods can detect a single leprosy bacillus, interpreting results, particularly in highly endemic areas, is difficult. Careful clinicopathologic correlation is essential when basing a diagnosis on DNA findings.³³⁸ Multiplex PCR has also been piloted to detect early cases of leprosy in community-based contact tracing, and was more sensitive than acid-fast bacillus smear examination.¹⁴ One pediatric study showed that, whereas slit-skin acid-fast bacillus smears were positive in only 20% of cases, PCR was positive in almost 90% of children with borderline and lepromatous leprosy and 72% of leprosy cases overall.¹⁵¹ Specimens for PCR amplification should be preserved in 70% ethyl alcohol.^{44,96,116}

Historically, mouse footpad (MFP) assays have been used to screen for *M. leprae* drug resistance; however, the MFP assay is time-consuming (often requiring more than 6 months before result availability). Molecular targets for drug resistance have been identified. Resistance to rifampin (similar to *M. tuberculosis*) is associated with the *rpoB* gene, fluoroquinolone resistance with the *gyrA* gene, and dapsone resistance is associated with the *folP1* gene.²³¹ In one study, sensitivity was higher for PCR than for MFP.²⁹⁸ A newer modality, which uses reverse hybridization DNA strips, is now commercially available. This assay, the GenoType Leptrae DR, evaluates for mutations in *rpoB*, *gyrA*, and *folP*. In one study conducted in 120 strains, concordance with PCR and MFP assays was 100%.³⁹

The differential diagnosis of leprosy in children is an extensive subject and can be discussed only briefly here. Superficial mycoses and postinflammatory changes commonly are confused with early leprosy. Changes in pigmentation may be caused by scars, birthmarks, and actinic dermatitis. In areas where dermal filariasis is endemic, vague macules in a black-skinned patient may appear identical to the early macules of leprosy.^{30,192,202} Among the many infiltrated lesions of the skin that can resemble leprosy are leishmaniasis, lymphoma, granuloma annulare, granuloma multiforme (Mk disease), lupus erythematosus, psoriasis, pityriasis alba, rosea, and versicolor, sarcoidosis, seborrheic dermatitis, vitiligo, and neurofibromatosis. Histoid leprosy especially mimics other diseases—von Recklinghausen lesions, molluscum, erythema nodosum, subcutaneous rheumatoid nodules, and nodular syphilis.^{297,329} Peripheral neuropathies that may simulate leprosy are those seen in Morvan syndrome, syringomyelia, lead intoxication, diabetes mellitus, primary amyloidosis of nerves, and familial hypertrophic neuropathy. Pure neuritic leprosy is in the differential diagnosis of hypertrophic neuropathies, such as those caused by amyloidosis and chronic relapsing polyneuritis, and progressive hypertrophic interstitial lepromatous leprosy frequently gives false-positive reactions for syphilis.

Prognosis

Without chemotherapy, the prognosis in all patients except those with limited and self-healing disease potentially is poor. Patients with

borderline or advanced tuberculoid leprosy frequently become mutilated because of neuropathy. Borderline patients can decline toward lepromatous leprosy. In patients with lepromatous leprosy, the disease is progressive and can cause death from laryngeal obstruction. Secondary amyloidosis is a frequent late sequela. Blindness may result from repeated episodes of iridocyclitis or ocular desiccation and/or keratitis from eyelash anomalies. Nerve damage as identified by electrophysiologic tests may be more widespread than realized on clinical examination. In one series of adults with multibacillary leprosy, before treatment, 92% of patients had abnormal nerve conduction studies, with sensory nerves being more involved than motor nerves (52% vs. 37%), and almost two-thirds of patients had involvement of five or more sensory or motor nerves or both.⁴⁰ General debility and deformity eventually prevent gainful employment in many patients. Additionally, the stigma associated with the disease may have pervasive effects on the lives of affected children and adults.

If therapy is started early, the prognosis usually is excellent, and deformity and mutilation are prevented. Even after receiving successful chemotherapy, however, some patients continue to experience significant neuritis and loss of peripheral nerve function. Sometimes this “silent neuropathy” goes unnoticed by the patient and the physician.^{65,359} Appropriate early attention to anesthetic hands and feet and restoration of function by reconstructive surgery can prevent most mutilation.

The lepromin test is a valuable prognostic tool because it measures the cell-mediated immunity potential of the host to acquisition of infection by *M. leprae*.¹⁴⁵ Patients with early macular lesions who are lepromin negative have a poorer prognosis than patients who are lepromin positive if treatment cannot be administered. Histopathologic evaluation made before instituting chemotherapy is important for determining the prognosis and, if available, should not be neglected.

Treatment

When a diagnosis of leprosy is established, chemotherapy must be initiated and appropriate measures must be instituted for preventing

or correcting deformity in patients with neurotropic changes.^{47,103,173} The three chemotherapeutic agents most commonly used are dapsone, clofazimine, and rifampin.²²³ Although the WHO recommends only clinical findings for assessment of the therapeutic response in field programs, clinicians may wish to use additional evaluations. The effectiveness of chemotherapy is assessed readily in patients with lepromatous or near-lepromatous leprosy by the staining quality of *M. leprae* in skin smears. The response to chemotherapy in patients with tuberculoid leprosy and most borderline patients is determined by the clinical response and by histopathologic evaluation. Viability of *M. leprae* in tissues is assessed in unusual cases in the mouse footpad.

Combined chemotherapy is being accepted increasingly for all forms of active leprosy. Although experimental data are limited,³¹⁰ multidrug therapy has replaced monotherapy (Table 98.2).^{74,379} Monotherapy with any chemotherapeutic agent is not advised for concern for selection of resistant isolates. As previously discussed, conventional methodologies for leprosy drug susceptibility are cumbersome, leading to increased emphasis on detection of resistance using molecular modalities. This has also resulted in increased surveillance capabilities. During 2010, sentinel surveillance data from nine nations (Brazil, China, Colombia, India, Myanmar, Pakistan, the Philippines, Vietnam, and Yemen) evaluated drug resistance in patients with relapsed multibacillary leprosy. Of 88 samples tested for drug resistance, 9 were dapsone resistant, 1 was rifampin resistant, and none was fluoroquinolone resistant. No isolate was found to be multidrug resistant.³⁷⁶ More recent reports from China have found that, among 85 isolates, 1.5%, 8.8%, and 25.9% had mutations associated with resistance to clofazimine, rifampin, and ofloxacin, respectively, and 3.5% of isolates were multidrug resistant.¹⁸¹

Dapsone

Dapsone, a bacteriostatic sulfone antimetabolite for *M. leprae*, was the first chemotherapeutic agent found to be effective; it was first used in 1941 in Carville, Louisiana.⁹⁰ The drug usually is given orally at 1 to 2 mg/kg per day as a single daily dose. The adult dose is 100 mg daily,

TABLE 98.2 Suggested Dosing Regimens for Leprosy From the World Health Organization^{378,379} and National Hansen's Disease Program²³³

Leprosy Classification	Drug	DOSE ^d			Duration
		Age <10 y	Age 10–14 y	Age ≥15 y	
Paucibacillary ^a	Dapsone	1–2 mg/kg/day	1–2 mg/kg/day	100 mg daily	WHO: 6 months
	Rifampin	10–20 mg/kg/day	10–20 mg/kg/day	600 mg daily (NHDP) 600 mg monthly (WHO)	NHDP: 12 months
Multibacillary ^b	Dapsone	1–2 mg/kg/day	1–2 mg/kg/day	100 mg daily	WHO: 12 months
	Rifampin	10 mg/kg/day	10 mg/kg/day	600 mg monthly (WHO) 600 mg daily (NHDP)	NHDP: 24 months
	Clofazimine ^c	50 mg biweekly + 100 mg monthly (WHO) 1 mg/kg/day (NHDP)	50 mg every other day + 150 mg monthly (WHO) 1 mg/kg/day (NHDP)	50 mg daily (NHDP, WHO) ± 300 mg load monthly (WHO)	
	Minocycline (second line for dapsone or clofazimine)	25 mg monthly if <15 kg; 50 mg monthly if 15–30 kg (WHO) ND (NHDP)	50 mg monthly (WHO) ND (NHDP)	100 mg monthly (WHO) 100 mg daily (NHDP)	Extend multidrug therapy to 2 years ³⁴⁷
	Ethionamide (second line for clofazimine)	50–75 mg daily if <15 kg, 150–175 mg daily if 15–30 kg (WHO) ND (NHDP)	275–375 mg daily (WHO) ND (NHDP)	275–375 mg daily	
	Ofloxacin (second line for clofazimine or rifampin)	100 mg monthly if <15 kg, 200 mg monthly if 15–30 kg (WHO) Not recommended (NHDP)	200 mg monthly (WHO) Not recommended (NHDP)	400 mg monthly (WHO) 400 mg daily (NHDP)	

Because the National Hansen's Disease Program may change its recommendation for patient management, clinicians in the United States are advised to seek consultation prior to treating any patient with leprosy (800-642-2477, 225-756-3709; Mtemple@hrsa.gov; www.bphc.hrsa.gov/nhdip/).

^aTuberculoid leprosy, borderline-tuberculoid, and indeterminate.

^bLepromatous, borderline, and borderline-lepromatous.

^cHigher doses may be used for patients with erythema nodosum leprosum.

^dPediatric dosing should never exceed adult maximum. Approximate pediatric dosing,¹⁵⁰ as a percentage of adult dosing, can be estimated as 25% for children <15 kg, 50% if 15–30 kg, 75% if 30–45 kg, and 100% if >45 kg.

ND, No dosing information available; NHDP, National Hansen's Disease Program; WHO, World Health Organization.

and in the United States, dapsone is available as 25- and 100-mg tablets. The effect of dapsone on the bacilli is slow; 3 to 6 months of treatment is necessary to render bacilli from patients with lepromatous leprosy noninfectious for the mouse footpad. Sulfone-resistant strains of *M. leprae* are being detected with increasing frequency^{359,360,376}; monotherapy with dapsone is not recommended. Dapsone usually is well tolerated but may provoke one or more of the following signs or symptoms: fever, exfoliative dermatitis, generalized lymphadenopathy, hepatosplenomegaly, or psychosis. Laboratory findings may include leukocytosis, hemolytic anemia, eosinophilia, or elevated bilirubin and serum transaminases.³ Children should be screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency before initiation of therapy.

Rifampin

Rifampin is a bactericidal antibiotic inhibiting bacterial DNA-dependent RNA polymerase. A single large dose can render a highly positive lepromatous patient noninfectious within 1 week. Available formulations include capsules (150 and 300 mg) and a parenteral formulation. The dose for persons 15 years of age and older is 600 mg, with pediatric doses of approximately 10 mg/kg given as a single daily dose. Optimal doses for children with leprosy have not been reported. Adult doses range from 300 to 600 mg daily.³⁷⁰ Many side effects (e.g., hepatotoxicity, myalgias, thrombocytopenia) and drug-drug interactions with rifampin have been described, and the relevant literature must be consulted.³⁵ Rifampin-resistant leprosy has been reported.^{140,366} Rifampin is not felt to interact with dapsone or clofazimine.

Clofazimine

Clofazimine (Lamprene) is a bacteriostatic riminophenazine dye that has anti-*M. leprae* and antiinflammatory activities, of particular utility for patients with erythema nodosum leprosum reactions, and is part of multidrug therapy for multibacillary leprosy (in conjunction with dapsone and rifampin).⁹¹ The mechanism of action may involve enhancement of oxygen-dependent killing of *M. leprae* and binding to bacterial DNA. Clofazimine is available in 50- and 100-mg capsules, but is not commercially available in the United States (the National Hansen's Disease Program [NHDP] can facilitate US practitioners obtaining the medication). The WHO recommends clofazimine for patients with multibacillary leprosy.³⁷⁹ The lower dosages are used for maintenance therapy when a good clinical response has been achieved, and the higher dosages (up to 100–300 mg daily in two or three divided doses) may be needed to control erythema nodosum leprosum; these regimens have not been well studied in children. The major adverse reactions to clofazimine are hyperpigmentation of skin and enteritis. Enteritis is experienced only at the higher dosages generally used for erythema nodosum leprosum. The pink to black hyperpigmentation is most prominent on exposed body parts, usually begins within 1 to 4 weeks of therapy initiation, subsides with the clinical improvement in leprosy, and resolves within a year of drug withdrawal. Pigmentary staining of the cornea and lacrimal fluid have been reported, but infrequently affects visual acuity. Ichthyosis can also be seen, especially in dry climates. This can be reduced by application of skin moisturizers and decreasing exposure to bright sunlight. Although two instances of clofazimine-resistant *M. leprae* infection have been reported, the validity of these observations is uncertain.^{157,357} Cross-resistance between clofazimine and dapsone or rifampin has not been reported. For some time, clofazimine has been considered safe in pregnancy, but one report described three neonatal deaths in 15 observed pregnancies.⁹² Whether the drug was associated with the deaths was not established.

Fluoroquinolone Therapy

The last decade has seen use of fluoroquinolones, primarily ofloxacin, for leprosy after nonhuman animal studies and early clinical studies in humans demonstrated that this class of drugs was more effective against *M. leprae* than dapsone and clofazimine. One Brazilian trial¹⁵⁹ of patients with multibacillary leprosy found that short-course treatment with short-course rifampin-ofloxacin therapy had higher failure rates than the recommended WHO regimen (below) and that addition of 1 month of daily ofloxacin to the 12-month WHO regimen did not increase efficacy. However, a study of a 4-week course of ofloxacin and rifampin

for paucibacillary disease¹⁰ found that short-course therapy was efficacious and few patients had relapses when compared to standard multidrug therapy. As such, the role of fluoroquinolones in the treatment of leprosy remains unclear. In addition, the optimal dose of fluoroquinolones in children is unclear, as children often require a higher milligram per kilogram dose than adults to achieve similar serum concentrations.

Multidrug Therapy

Because of the existence of drug-resistant *M. leprae*, combined drug regimens are mandatory for the treatment of all forms of leprosy.^{87,310,358,359}

Combined drug therapy minimizes development of drug-resistant strains of *M. leprae* and may eliminate some “persisting” organisms. Persisting *M. leprae* are viable bacilli that can be isolated in small numbers from patients who are clinically responding well to therapy. These persisting *M. leprae* bacilli are sensitive to the drug in question when tested in the mouse footpad and may account for relapses when treatment is discontinued. Persisting *M. leprae* organisms have been detected after 5 years of therapy with rifampin, 6 years of clofazimine therapy, and 22 years of dapsone therapy.

In 1982, a WHO study group recommended the multidrug therapy (MDT) regimens that are described hereafter.³⁷¹ The MDT regimens were designed primarily for field programs, and they use pulsed supervised monthly rather than daily rifampin.²⁰ MDT is well tolerated, and compliance in large-scale control programs has been satisfactory. The efficacy of MDT has been promising.^{42,359} In two surveys involving approximately 112,000 patients with multibacillary disease monitored for 9 years after receiving therapy, the cumulative risk for relapse was 0.77%. Anecdotal descriptions of certain groups of highly bacilliferous patients with relapse rates of 20% and recurrences developing 5 years or more after therapy have been reported.¹⁴² These and other results suggest that therapeutic regimens for multibacillary patients should be given for longer than 2 years. In most reports, relapse rates in paucibacillary patients exceed those in multibacillary patients. The potential for relapse after receiving MDT regimens must await long-term, large-scale follow-up results.^{141,319} Factors associated with relapse include having declining IgG antibodies against PGL-1, requiring treatment for reactions, and having lepromatous leprosy.^{83,119} Peripheral neuropathy sometimes persists after completion of these therapeutic regimens.^{4,127}

The trend since 2001 has been to reduce the duration of treatment and change the therapeutic regimens—even to the extreme of a single-dose regimen composed of rifampin, ofloxacin, and minocycline (ROM) for single-lesion therapy. One meta-analysis concluded that single-dose ROM was less effective than multidrug therapy for paucibacillary leprosy.³⁰¹ Many of these innovations are interwoven into the WHO Elimination of Leprosy Program and have provoked critical concern by some authorities.^{97,182,229,317} The NHDP recommends daily therapy,²³³ as opposed to the intermittent dosing recommendations for rifampin recommended by the WHO for resource-limited settings. Both WHO- and NHDP-recommended regimens are listed in Table 98.2. Laboratory monitoring should include baseline complete blood count, transaminases, bilirubin, blood urea nitrogen, creatinine, and calcium and then repeated every 3 months.

Other Drugs Under Investigation

Recent years have seen escalating use of fluoroquinolones, macrolides, tetracyclines, and ethionamide for patients intolerant of standard regimens.^{108,109,117,144} Knowledge of the *M. leprae* genome will potentially lead to targeted drug development after computational genomic analysis. For example, one study identified several genes mapping to peptidoglycan cell wall biosynthesis; these *Mur* genes have no homolog to human genes, decreasing the risk for cross-reactivity of agents.³⁰⁴

Treatment of Reactions

Patients experiencing a reaction should be observed daily in the early stages and hospitalized if the symptoms are severe. Formerly, specific therapy was stopped or the dosage reduced during reactions, but these measures are no longer recommended.³⁷¹ Damage to eyes and neurotropic changes may ensue rapidly without immediate attention. Nerve tenderness and function must be assessed frequently during reactions. Acute inflammation of isolated lesions without damage to nerves is likely to

be of little consequence except for cosmetic considerations, but the patient should be monitored closely. It is difficult for clinicians to identify children who may be at increased risk for a leprosy reaction. One retrospective cross-sectional study identified laboratory factors associated with increased risk of reactions. These included PCR positivity, anti-PGL-1 ELISA, leukocytosis, thrombocytopenia, and elevated lactate dehydrogenase.⁷

Reversal (type 1) reaction. Patients with painful, tender nerves must receive immediate care, usually in the hospital. Analgesics are given, and the affected area is rested. Large daily doses of corticosteroids are started and tapered to a minimal effective dose until the reaction subsides. Conversion to alternate-day steroid regimens may be attempted when long-term treatment is necessary. One randomized, double-blind trial compared methylprednisolone with placebo in conjunction with oral corticosteroids for adults with type 1 reactions; persons treated with methylprednisolone were less likely to have nerve damage and recurrent type 1 reactions.³⁵³ However, one meta-analysis indicated that, although corticosteroids may be useful for treating acute nerve damage, long-term benefit may not be seen.^{40,341} A 12-week course of topical tacrolimus was used in one case of steroid-refractory type 1 reaction in a child with borderline lepromatous leprosy, with resolution of all skin lesions.²⁸² Some clinicians use clofazimine for chronic reversal reactions, but it is not recommended for the initial treatment of reactions with acute neuritis. For reactions, clofazimine probably is consistently efficacious only for erythema nodosum leprosum (ENL).¹³⁶

Erythema nodosum leprosum (type 2) reaction. Mild erythema nodosum leprosum (ENL) is treated with analgesics; more severe disease is treated with corticosteroids, thalidomide, clofazimine, or other drugs.³⁴⁸ Pediatric doses of thalidomide in ENL have not been established, but the initial adult dose is 100 mg four times daily followed by a minimal effective dose, usually 100 mg daily. In the United States, thalidomide is available for ENL under the Celgene REMS Program (<http://www.celgeneriskmanagement.com>). The teratogenic action of thalidomide demands that appropriate measures be taken in the treatment of fertile women. For the rare patient who does not respond to thalidomide or in fertile women, corticosteroids or clofazimine is used. Corticosteroids, if used, are administered in the usual dosage schedules (1 to 2 mg/kg daily), beginning with large doses and tapering to a minimal effective level. The total duration of corticosteroid therapy is unclear; one study found that patients treated for 5 months were less likely to have recurrence than those treated for only 3 months.³⁵² One systemic review indicated that clofazimine was superior to thalidomide or corticosteroids, but analysis was hindered by variation in the quality of studies in the pooled data.³⁴⁰ Clofazimine is effective in most patients with erythema nodosum leprosum and does not have the disadvantages of thalidomide or corticosteroids. The antiinflammatory action of clofazimine is not manifested until after 4 to 6 weeks of continuous use. The dosage must be adjusted to the minimal effective level, and high doses are recommended by the WHO for erythema nodosum leprosum reactions.³⁷⁹ A few studies suggest that pentoxifylline or pentoxifylline plus clofazimine is effective.^{236,328,361} While clofazimine provides sustained improvement, it acts slowly; in contrast, pentoxifylline is more effective in reducing initial severity.²⁷⁷ However, one randomized double-blind clinical trial comparing thalidomide (300 mg) to pentoxifylline (1.2 g) administered daily for 1 month found that thalidomide was more effective in treating ENL. Nonetheless treatment with pentoxifylline seemed to help with limb edema and constitutional symptoms.²⁸³ One case report described the successful treatment of a chronic erythema nodosum leprosum reaction with a 6-week course and slow taper of the TNF inhibitor etanercept.²⁵⁹ A recent case series demonstrated that 80% of adults with ENL who had failed corticosteroids responded to minocycline (100 mg/day for up to 3 months). The potential mechanism of action is that minocycline has immunomodulatory, antiinflammatory, and neuroprotective effects.²³²

Iridocyclitis requires emergency measures. Local corticosteroids must be added to systemic antiinflammatory regimens. Ophthalmologic consultation should be obtained.

Prevention

Precise recommendations for the prevention of leprosy in individuals have not been formulated. Control programs today are based on the

general principles that (1) the number of contagious patients is reduced by chemotherapy and (2) the surveillance of contacts detects early leprosy. To accomplish these goals, appropriate education of the public and medical personnel and population surveys in areas of higher prevalence must be implemented. In endemic areas, improved housing probably is a highly important preventive measure by reducing close contact of patients with healthy individuals. In health care settings, infection control precautions include hand hygiene for all patients with lepromatous leprosy. Standard precautions are indicated for the hospitalized patient. Leprosy is a reportable disease in the United States.

Chemoprophylaxis

Chemoprophylaxis for close contacts was first attempted with dapsone, showing efficacy rates ranging from 34% to 99%,³¹⁹ but was not recommended for large populations⁶⁵ given concerns that long-term use would select for dapsone-resistant isolates.³⁷⁰ More recently, rifampin has been evaluated for chemoprophylaxis. One study on leprosy hyperendemic Indonesian islands used rifampin every 3.5 months, showing protective efficacy of 75% to 90%.⁹ A cluster randomized trial in Bangladesh showed that single-dose rifampin had protective efficacy of 57% within 2 years of administration.²²⁰ Single-dose rifampin chemoprophylaxis is both culturally acceptable⁹³ and cost-effective, particularly in social contacts and neighbors of cases.¹³⁵ However, concern exists that single-dose rifampin chemoprophylaxis may select for rifampin-resistant *M. leprae* isolates.

Vaccination, Immunoprophylaxis, and Immunotherapy

Vaccines composed of heat-killed whole *M. leprae* (from experimentally infected armadillos) have been found to be safe and to induce delayed-type hypersensitivity to *M. leprae* in a high percentage of lepromin-negative individuals. Several other vaccines based on cultivable mycobacteria (*Mycobacterium vaccae*, *Mycobacterium w*, and the Indian Cancer Research Centre bacillus) induce similar responses.^{22,158,322} Vaccine progress has been thwarted by the need for extended follow-up observations²⁴ and concern that vaccines containing only *M. leprae* would not be protective given that infection-induced immunity is infrequently observed for leprosy. Consequently, combined vaccines of killed *M. leprae* and live bacillus Calmette-Guérin (BCG) have been studied. Such vaccines convert lepromin-negative contacts of patients with leprosy to positive reactors and upgrade patients with lepromatous leprosy toward the tuberculoid region of the disease spectrum.^{52,207}

BCG immunization alone had a protective effect of 26% in one meta-analysis; this analysis also found that age at immunization did not affect efficacy and that receipt of a second dose of BCG vaccine was more protective for leprosy than receipt of a single BCG dose.³⁰² Subsequent studies have had variable results.³⁷¹ Combining BCG with killed *M. leprae* did not protect against leprosy.^{54,159} BCG vaccination was combined with single-dose rifampin for close contacts of leprosy patients in Bangladesh, showing a protective effect of 80%.²⁹² The WHO does not recommend BCG vaccination for the prevention of leprosy.¹⁹

Leprosy vaccines as adjuvant to multidrug therapy also have been attempted in multibacillary leprosy patients. *Mycobacterium w* vaccine given in 3-month intervals (up to eight doses) was associated with improvement in clinical scores and decline in bacteriologic indices for up to 2 to 3 years, but no impact was seen on clinical relapse or incidence of neuropathy after this interval. Rates of type 1 reactions were more common in the vaccine group in contrast to a placebo group receiving multidrug therapy alone.³⁰⁵

Elimination

In 1991, the World Health Assembly defined leprosy elimination as a prevalence of fewer than 1 case/10,000 persons. By this definition, only three nations with populations over 1 million have yet to attain this goal: Brazil, Nepal, and Timor-Leste (East Timor).³⁷ However, pockets of high endemicity exist in several countries: Angola, Brazil, the Central African Republic, the Democratic Republic of the Congo, India, Madagascar, Mozambique, Nepal, and Tanzania. The prospect of truly eliminating leprosy is poor due to several factors. First, a zoonotic focus^{203,332} can lead to continued introduction into human populations. Second, vaccination development efforts have been hindered by poor

correlates of immunity. Third, surveillance for new cases can be hindered by the stigma attached to the disease. This can lead to either failure to seek medical attention or seeking medical attention in alternative medical settings, where reporting of cases may not occur.¹³⁹ One study modeled the impact of various interventions on leprosy incidence rates. Variables included passive versus active case detection, multidrug therapy, contact tracing, BCG vaccination of infants, early diagnosis of subclinical infection, and chemoprophylaxis. A multifaceted approach including BCG vaccine coverage, contact tracing, early diagnosis, and chemoprophylaxis of household contacts seemed to reduce leprosy incidence rates most substantially.⁹⁸ However, these strategies would require an infrastructure and investment that fall outside the health budgets of many developing nations. Given the lack of tools to diagnose subclinical infection, long treatment duration, and continued uncertainty regarding aspects of patterns of exposure, modes of transmission, persistence of leprosy in treated cases, and early host response, many experts believe that control, rather than eradication, should be the goal.³¹⁸

BURULI ULCER

Mycobacterium ulcerans causes indolent, necrotizing cutaneous ulcers that are known classically as *Buruli ulcers*.^{183,339} Other names for these lesions include Bairnsdale or Searles ulcer in Australia, and Kumusi ulcer in Papua New Guinea. Today, researchers recognize that many infections with *M. ulcerans* are not manifested as ulcers and that *M. ulcerans* infection is a technically more appropriate name for the disease. The WHO has recognized Buruli ulcer as a reemerging infectious disease in western Africa with an important public health impact.³⁷⁴

Organism

The organism was first isolated in 1948.¹⁸⁴ *M. ulcerans* is strongly acid-fast, with an optimal growth temperature of 30°C to 33°C (86°F–91.4°F) on routine mycobacteriologic media such as Löwenstein-Jensen medium. Unlike *M. marinum*, *M. ulcerans* is slow growing, nonphotochromogenic, microaerophilic, and heat sensitive.^{208,246}

Comparative genomic analysis indicates that *M. ulcerans* arose from *M. marinum*, with which it shares 98% genomic homology.⁷¹ *M. ulcerans* is the only mycobacterial pathogen of humans known to elaborate a necrotizing, immunosuppressive exotoxin, mycolactone.^{62,263,313} The mycolactone mechanism of action is unclear, but evidence exists for the toxin triggering apoptosis^{122,354} and decreasing satellite cell proliferation.¹³¹ Variations in the 3' end of the 16S rRNA gene sequence are related to geographic origin and are used to divide the organism into African, American, Asian, and Australian strains.²⁵⁶

Transmission and Epidemiology

Endemic foci of *M. ulcerans* infections usually appear in rural settings near permanent wetlands in warm countries, especially in terrain subject to seasonal flooding. Reports of patients with Buruli ulcers have come from at least 33 countries, principally in the tropics.³⁷⁵ A few patients live in nontropical climates, such as China,⁸⁹ Japan,³³³ and southern Australia.³⁴³ Today, the largest numbers of reported patients live in West Africa (Cameroon, Côte d'Ivoire, the Democratic Republic of the Congo, and Ghana report the most cases).³³⁹ In these countries, the disease is reemerging rapidly, with an estimated total annual incidence exceeding 2200 patients from 12 of the 33 nations. Other countries in which the disease is known to be endemic include Angola, Equatorial Guinea, French Guiana, Gabon, Indonesia, Malaysia, Papua New Guinea, Peru, Suriname, and Uganda.^{66,129,200,250} In the Western Hemisphere, cases have been reported primarily in French Guyana, but also in Brazil, Mexico, Peru, and Suriname.³⁷⁵

Observers attribute this reemergence to environmental factors such as deforestation, artificial topographic alterations (e.g., dams and irrigation systems),^{69,185} increasing populations engaged in basic manual agriculture in wetlands, and possibly climactic changes.²¹⁰ These manmade environmental modifications may lead to changes in water temperature or turbidity, potentially protecting *M. ulcerans* biofilms.¹⁹⁹ In North America, two cases of Buruli ulcer were reported in 2005 in central Mexico, the nearest location to the United States to date.⁴⁸ Individuals of all ages are affected, but the highest frequencies are in children 15

years of age or younger—approximately 50% to 75% of all cases.¹⁸⁹ A second peak occurs in the seventh to eighth decade of life, suggesting that latent infection can reactivate with age.⁶⁷ The sexes are affected equally, and a racial predilection is unknown.⁶⁷ Seasonal variations in incidence occur in some foci.^{125,266} Approximately 80% of the lesions are on the limbs, with the highest frequencies involving the lower extremities.

Although the ultimate source of *M. ulcerans* remains obscure, the organism has been discovered in aquatic insects, such as water bugs, firefly larvae, and beetles, and obtained from stagnant water in endemic areas of West Africa, as well as newly dammed areas in Cameroon.^{185,188,255} In some cases, the organisms were found only in the salivary glands of aquatic insects, supporting the notion that insect bites may play a role in transmitting *M. ulcerans*.^{186,187} Adult mosquitoes trapped outside Victoria, Australia also had detectable *M. ulcerans* DNA. *Aedes* spp. were most likely to have DNA identified, followed by *Anopheles* spp.; lowest detection was seen in *Culex* spp.¹⁷⁶ This may explain the observation that having daily contact with a natural water source was a risk factor for Buruli ulcer disease according to one study in Benin,³²⁰ and that lower rates of Buruli ulcer were seen in higher altitude villages in Benin.³²¹ Wading into rivers was a risk factor for Buruli ulcer in one study, which also found that the most common lesions occurred on uncovered extremities²⁵⁸; both also suggest transmission from biting aquatic insects. A group from Melbourne, Australia, evaluated both environmental sources and nonhuman animal (koala, opossums, small rodent) feces for *M. ulcerans* DNA.^{82,104,216} *M. ulcerans* DNA was not detected in fecal samples from Buruli ulcer patients, suggesting that the human gastrointestinal tract is not likely to be a significant reservoir.²⁸⁷

Buruli ulcer rarely, if ever, is contagious. The distribution of patients, even in highly endemic foci, is random, suggesting that each patient is exposed to environmental sources, such as swamps where villagers work their gardens and obtain water for domestic use and especially where children play. The mode or modes of transmission to humans have not yet been delineated completely; however, the most plausible route is by trauma at sites of skin recently contaminated by *M. ulcerans*.^{79,209} Many patients give a history of specific antecedent penetrating trauma at the site of their initial lesion, which may include wounds from a gunshot or land mine, thrown stones, hypodermic injection, or even a human bite (Fig. 98.14).⁷⁰ The organism may be spread by aerosol from the surface of ponds or be carried by fomites or insects to skin surfaces.

FIG. 98.14 A major Buruli ulcer in the deltoid area of a 12-year-old Angolan boy. This pristine ulcer developed 3 months after a documented hypodermic anticholera vaccine injection at this site. Typical Buruli ulcer features are represented—undermining of borders, necrotic base, and induration of the adjacent skin.

Insects may introduce *M. ulcerans* into the skin, but this means of transmission has not been proved. Although proposed by some authorities, transmission by nasorespiratory passage with a subsequent bacteremia seems to be unlikely.

Pathogenesis and Pathology

Three properties determine the pathologic features of early *M. ulcerans* infection: optimal growth at 30°C to 33°C (86°F–91.4°F), slow growth rate, and elaboration of the toxin mycolactone.³¹³ The temperature requirement tends to favor the development of lesions in the skin (versus deeper tissues). The slow growth rate results in slowly progressive lesions. Mycolactone destroys tissues and suppresses immune responses. The spectrum of clinical and histopathologic forms of infection suggests that some patients have innate resistance, or resistance develops soon after infection is acquired, whereas others acquire resistance later or, occasionally, never.

Many of the differences in pathogenicity between *M. ulcerans* and *M. marinum* may be explained by the presence of mycolactone in the former species. Mycolactone has broad-spectrum cytotoxic activity for a variety of cell types. It can cause apoptosis, vasculitis, and thromboses. Mycolactone is also thought to inhibit TNF- γ and IL-2 production and augment IL-10 production.^{2,58,168} These activities partly explain the immunologic unresponsiveness and reduced inflammatory reaction at the site of the lesion. One study in Benin found that the rate of hemoglobinopathies was almost seven times higher in Buruli ulcer osteomyelitis patients than the general population, suggesting these disorders facilitate the growth of the organism in bony matrices.²³⁰

Based on the current understanding of the natural history of *M. ulcerans* infection, pathogenesis may proceed as follows: after inoculation of the etiologic agent deep into the skin or subcutaneous tissue, a latent phase occurs during which the mycobacterium proliferates slightly, probably initially intracellularly,²⁴³ and begins to elaborate small amounts of toxin that causes necrosis, especially of fatty tissue. During this necrotic phase, no significant cellular response occurs.^{49,75}

In some patients, at this stage, a subcutaneous nodule begins to develop, with clusters of *M. ulcerans* in the center surrounded by a zone of necrosis. In highly resistant patients, this lesion may self-heal, perhaps without ulceration, or form a small, sharply delineated ulcer. In others, the skin is undermined by the necrosis and eventually breaks down into larger ulcers with widely undermined skin. In the least resistant individuals, a nodule never develops and the necrosis spreads rapidly and widely to cover large body surface areas, but ulceration, if it occurs at all, is a late event.

Eventually, the necrotic stage ceases in most patients, either because the toxin is neutralized or because production is interrupted. At this time, a granulomatous stage begins to develop, followed by healing and scarring. Some of the variability in clinical presentation and progression of the disease may be related to heterogeneity in the *M. ulcerans* genome and in the plasmid that encodes the production of mycolactone.^{227,325,326}

Histopathologic findings are characterized by extensive coagulation necrosis of the soft tissues (Fig. 98.15)¹¹⁸ masses of acid-fast bacilli, marked edema, and extensive vasculitis. Fat cells enlarge and die, with only their cellular ghost outlines remaining (Fig. 98.16). The dermis and surrounding tissue seldom contain acid-fast bacilli. Lesions sometimes provoke a reactive (contiguous) osteitis that leads to necrosis of cortical bone and osteomyelitis. Metastatic lesions may develop in the skin and bone from bacteremia and produce skin lesions distant from the original lesion and frequently focal or multifocal osteomyelitis. Regional lymph nodes may show massive necrosis and contain large numbers of acid-fast bacilli. Visceral organs are not known to be involved, but no necropsies of patients who died of disseminated disease have been reported.³³¹

Clinical Manifestations

Incubation and Forms of Lesions

In one study of specific trauma related to lesions, the incubation period ranged from 2 weeks to 3 years, with a mean of 3 months.²⁰⁹ The following are the various forms of lesions of *M. ulcerans* infection according to WHO designations.³⁷⁶ Fig. 98.17 presents a proposed classification of

FIG. 98.15 Histopathologic section of the undermined edge of a major Buruli ulcer. Note the coagulation necrosis of the entire panniculus and fascia, and vasculitis with thrombosis of a blood vessel (arrow) (hematoxylin and eosin stain).

FIG. 98.16 High magnification of the necrotic panniculus of a Buruli ulcer showing dead fat cell "ghosts," coagulation necrosis, and masses of acid-fast bacilli (Ziehl-Neelsen stain).

the clinical forms of *M. ulcerans* disease and their possible interrelationships. The WHO also designates three categories of lesions. Category I consists of single lesions less than 5 cm in diameter; these may heal completely with medical therapy. Category II consists of a single lesion 5 to 15 cm in diameter; only some heal completely with medical therapy. Category III lesions encompass large (>15 cm diameter) lesions, lesions in multiple locations, osteomyelitis, or lesions in critical sites (e.g., ocular, genitalia, or breast). These lesions usually require combined medical and surgical therapy.^{378,375}

Papule. The papular stage has been described only in patients from Australia. These papules are painless, elevated, and measure up to 1 cm in diameter.

Nodule. Nodules are primarily subcutaneous and firm, measure approximately 2 cm in diameter, and are painless, although they are often pruritic. The overlying skin may be discolored. Although usually mobile, they can become attached both to the skin and to deeper tissues.³³⁴ This stage is the initial one in most Africans, and in the Kikongo language, the disease is called *mputa matadi* because the nodule is a "rock-hard lesion." Unlike ulcerative forms, acid-fast bacilli are aggregated in the center of nodules.³³⁴ Patients with nodular lesions have fewer functional limitations than other forms of Buruli ulcer disease.²⁹¹

Plaque. Plaques are firm, elevated, painless, well-defined lesions more than 2 cm in the largest dimension. Their borders are irregular. This stage often is the one in which physicians initially see the patient, but the lesion may or may not arise from a nodule. The skin over the lesion is reddened or discolored. These lesions may ulcerate in the late stages.

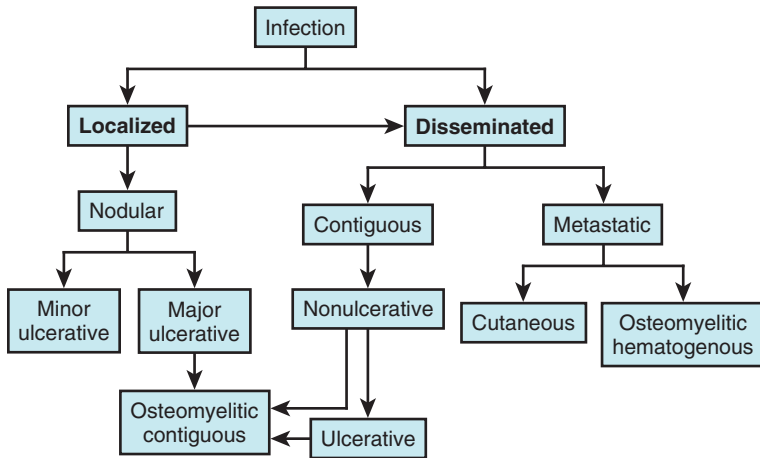

FIG. 98.17 Proposed classification of clinical forms of *M. ulcerans* infections, indicating possible progression of lesions after the initial cutaneous infection. Without treatment, lesions may self-heal at any stage or advance according to the schema.

FIG. 98.18 Edematous form of *M. ulcerans* infection in a 6-year-old Ghanaian girl after surgery to remove all necrotic tissue. There was never any ulceration. Note ablation of breast tissue.

These lesions are more likely to relapse after surgical therapy than ulcerative forms.¹⁶⁷

Edematous form. Most edematous lesions do not begin in the nodular stage but spread directly from the initial nidus of infection. Spread often is rapid and wide and covers entire limbs or major portions of the trunk (Fig. 98.18). This type of lesion is characterized by diffuse nonpitting swelling and vague margins. Lesions are firm and frequently painful, with changes in color and scaling on the skin surface. These lesions, along with plaques, are more likely to relapse after surgical therapy than ulcerative forms.¹⁶⁷

Ulcerative forms. When fully developed, pristine ulcers have undermined edges surrounded by a zone of induration and often desquamation of the epidermis (see Fig. 98.14). In the base of the ulcerated area, a whitish necrotic slough and sometimes eschar develop. An oily exudate frequently oozes from the dependent area. Old ulcers tend to begin healing in the uppermost part while activity continues in the dependent portion. Collections of fluid in this area probably continue to support the growth of *M. ulcerans*, which sustains progression of the lesion.

The ulcerative forms are divided into major and minor ulcers. Both forms tend to self-heal. A major ulcer is large and chronic and can form a contiguous osteomyelitis. Minor ulcers are small (1 to 2 cm in diameter), are sharply delineated, and heal early. Both ulcerative forms begin as subcutaneous nodules.

Bone Involvement

Contiguous osteomyelitis. Reactive osteitis occasionally develops beneath destroyed overlying skin and soft tissue, particularly with major ulcers. Bone becomes devitalized and necrotic, with the development of sequestra (Fig. 98.19).

FIG. 98.19 (A) *M. ulcerans* infection in a young Congolese boy. Note swelling and ulcer on dorsum of forearm. (B) Radiograph of forearm shows reactive osteitis, necrosis of cortex of distal end of the radius, and early sequestration with osteomyelitis.

Metastatic osteomyelitis. *M. ulcerans*-specific osteomyelitis develops in approximately 10% of all patients, underscoring that Buruli ulcer should always be considered a potentially systemic disease.²⁵⁷ Most likely, metastatic osteomyelitis is a result of lymphohematogenous spread of *M. ulcerans* from a distant, earlier cutaneous lesion (Fig. 98.20). The overlying skin ordinarily is intact, but swelling and inflammation occur over the site of bone involvement. If the condition goes untreated, a draining fistula usually develops. Osteomyelitis often requires amputation (Fig. 98.21).

Complications. Infection may traverse the deep fascia and damage tendons, nerves, joints, genitalia, and periorbital tissues, requiring subsequent enucleation of the eye. Healing leads to fibrosis and scarring, causing functional limitations.³²³ The scar may form keloids and often causes major contraction deformities, especially in lesions that cross joints (Fig. 98.22). Squamous cell carcinoma may develop in healed

FIG. 98.20 Ziehl-Neelsen–stained section shows metastatic osteomyelitis of the tibia in a 6-year-old boy in Benin. This lesion developed after *M. ulcerans* infection of the contralateral leg. Note necrosis of marrow, erosion of a trabecula, and many clusters of acid-fast bacilli.

FIG. 98.21 This 13-year-old girl in Benin initially had a cutaneous lesion of Buruli ulcer. Subsequently, metastatic spread to bones of the lower extremities occurred, resulting in bilateral high-thigh amputations. Note also the spread to bones of both wrists and left hand.

FIG. 98.22 Ghanaian adolescent girl with healed *M. ulcerans* infection that extended from the wrist to the shoulder. The scarring resulted in contraction deformities of the wrist and elbow and disuse atrophy of the entire extremity. Appropriate physiotherapy would have minimized these sequelae.

lesions, especially nonpigmented lesions.¹⁶¹ Skin grafting and physiotherapy prevent most of these complications. Most disease-related deaths result from septicemia, gas gangrene, or tetanus.

Human Immunodeficiency Virus and Buruli Ulcer

Studies indicate that HIV infection increases the risk of Buruli ulcer by sevenfold to eightfold,^{46,148} including a fivefold increase in HIV-infected children. HIV infection was also associated with more severe forms of Buruli ulcer: larger lesions and slower time to healing. Rapidly spreading *M. ulcerans* osteomyelitis has developed in several patients with AIDS.^{166,284} Chronic diarrhea in an HIV-infected adult has also been attributed to *M. ulcerans*.¹³²

Diagnosis and Differential Diagnosis

To an experienced observer, an accurate clinical diagnosis often can be made with ease.^{372,373} In the ulcerated forms, a Ziehl-Neelsen stain of exudate from the ulcer edge obtained with a cotton swab reveals clusters of extracellular acid-fast bacilli. Punch biopsies and fine-needle aspiration also have been used to obtain samples from nonulcerative lesions.³⁷⁸ Smears have an estimated sensitivity of 40%.³⁷⁵ The same material, obtained by swab after decontamination, may be used for culture on Löwenstein-Jensen or other suitable mycobacterial media. The incubation temperature must be 30°C to 33°C (86°F–91.4°F). If culture cannot be performed locally, transport media may be inoculated with material from the cotton swab and maintained at 4°C (39.2°F) while in transport to a specialized laboratory. The transport medium is composed of Middlebrook 7H9 broth supplemented with polymyxin B, amphotericin B, nalidixic acid, trimethoprim, azlocillin, and 0.5% agar. Cultures often require at least 6 to 8 weeks to grow and have a sensitivity of 20% to 60%, in part because of the fastidious temperature requirements of the organism.³⁷⁵ PCR is available and increasing in popularity and convenience.^{312,324} PCR sensitivity is high (approximately 98%).³⁷⁵ Tissue for histopathologic analysis should be obtained from the edge of the ulcer and must include all levels, including the fascia. Fixation in 4% buffered formalin is adequate. Histopathology has a sensitivity of 90% in experienced hands.³⁷⁵ Mycolactone can be found in peripheral blood and ulcer exudates (including exudates obtained at the conclusion of therapy) by high-performance liquid chromatography. Reduction in mycolactone is a proxy for response to therapy in nonhuman animal models.⁵¹ This modality may be more specific than smear microscopy, faster than culture, and more simple than PCR, making mycolactone an interesting target for diagnostic testing.

Some of the differential diagnostic possibilities are as follows:

Papules: Insect bites, verruca vulgaris, pityriasis, granuloma annulare
Nodules: Lipoma, sebaceous cyst, onchocerciasis, furuncle
Plaques: Leprosy, mycosis, necrobiosis, psoriasis
Edema: Bacterial cellulitis, actinomycosis, elephantiasis, pyomyositis
Ulcers: Tropical phagedenic ulcer, noma, stasis ulcer, leishmaniasis

Prognosis

Without treatment, Buruli ulcer often leads to deforming depressed scars, contraction deformities, or amputation. Delays in diagnosis are statistically related to the kind of Buruli ulcer disease. In one study, diagnosis for patients with nonulcerative forms was 32 days, 60 days for those with ulcerative manifestations, and 1 year for those with bony lesions.⁴¹ One study found that almost 60% of patients had functional limitations a median of 4 years after completing therapy. Functional limitations and risk factors for stopping work or school were collinear and included lesion over a joint or on hands or feet, female sex, older age, and presence of a persistent wound.³²³ The stigma of the deformities and the socioeconomic burden of the disease often are marked.⁸ With early appropriate treatment, including excision and grafting, the prognosis usually is excellent. Metastatic lesions and local recurrences occur frequently enough, however, to warrant vigilant follow-up.⁵ Paradoxical worsening of lesions while on appropriate antibiotic therapy has been noted, similar to immune reconstitution inflammatory syndromes seen for other mycobacterial infections. These are thought to be due to mycobacterial antigens and inflammatory cytokines released from clinically unrecognized bacterial foci.²⁷⁸

Treatment

Treatment options for Buruli ulcer include antibiotics and surgical intervention, the latter commonly used for category III lesions. In the preantibiotic era, wide local excision was commonly used.³³⁴ The WHO now recommends surgery as an adjunct to medical therapy, particularly to remove necrotic tissue, cover skin defects, and correct deformities resulting in functional limitations.³⁷⁸

The WHO recommends an 8-week course of rifampin 10 mg/kg (maximum 600 mg) daily and either streptomycin or amikacin 15 mg/kg (maximum 1 g) daily as first-line therapy for all forms of active disease.^{378,379} Intramuscular administration of aminoglycosides in children may be limited by the small muscle mass in many children. Macrolide therapy (clarithromycin, 7.5 mg/kg, maximum 1 g/day divided into two daily doses) has been substituted for aminoglycoside therapy during pregnancy. Monitoring for side effects is essential. For streptomycin, treatment should be stopped if hearing impairment or vertigo with nystagmus develops. For rifampin, treatment should be stopped if hepatitis, jaundice, or acute renal failure occurs, side effects that generally are associated with intermittent therapy of more than 10 mg/kg. One randomized trial in Ghana for patients with ulcers less than 10 cm in diameter compared the WHO-recommended regimen to streptomycin and rifampin for 4 weeks, followed by rifampin and clarithromycin for 4 weeks; they found no difference in response to therapy acutely or at 1-year follow-up.²³⁷ An entirely oral regimen of 8 weeks of rifampin and clarithromycin was evaluated in a pilot study of 30 Beninese patients with lesions less than 10 cm in diameter. The treatment was well tolerated, and all patients had healed by 12 months without disease recurrence.⁴³ One Australian study combined with rifampin with either ciprofloxacin or clarithromycin; this entirely oral regimen was well tolerated with low rates of recurrence and relapse.¹⁰² The extent to which these studies would apply to patients with more invasive or multifocal disease is unclear.

If surgical intervention is chosen, to minimize the danger of development of *M. ulcerans* bacteremia, many surgeons prescribe clarithromycin and rifampin 1 to 2 weeks before performing surgery and have the patients continue antibiotic therapy for several weeks after surgery. Although reasonable, this antibiotic complement to surgery is not of proven efficacy. In preulcerative Buruli disease, bacilli may extend well beyond the apparent border of the lesion, and having positive margins may increase the risk of recurrence.¹²⁶ As such, margins of at least 2.5 cm are recommended,³³⁴ and the need for postoperative medical management in these cases is unclear.

Plaques and edematous forms are excised widely down to the fascia, or through the fascia if it is necrotic. Muscle usually is not damaged, but if so, the excision is extended into muscle. The lateral extent of excision often is difficult to determine. By careful palpation, the physician can establish an approximate limit of the disease. Exploratory incisions and blunt dissection may help determine the limit of induration and necrosis. Use of real-time PCR for determining the extent of disease is being evaluated.²⁷²

Very small ulcers can be excised and closed primarily, as for nodules. Large ulcers are excised widely. The required extent of surgery may be determined by exploratory lateral excision and blunt dissection. Split-skin autografting of surgical defects usually is performed after a bed of granulation tissue has formed. Postoperative care, including physiotherapy, should be designed to prevent contractures.

Bone lesions should be referred to specialists. Heat therapy without surgical excision has been successful for appropriate lesions, but must be applied assiduously, with all necessary controls.²⁰⁸ Recurrences after surgical treatment are frequent, but rates are not well established.⁶⁸

Prevention

In an endemic tropical rural setting where children usually are scantily attired, prevention of contamination of the skin from environmental sources is virtually impossible. Wearing long trousers seems to prevent development of infection.¹⁸⁹ Protected water supplies in villages would reduce exposure; however, such protective measures usually are futile in rural areas of developing countries. Standard precautions are indicated for the hospitalized patient. Buruli ulcer disease is not a reportable disease in the United States.

Vaccination with BCG has a moderate (40% to 50%) protective effect against *M. ulcerans* infections for 6 to 12 months,¹³⁴ although effect wanes with time and has been variable in both human and animal studies.^{50,251} One form of Buruli ulcer disease for which BCG appears to have a sustained protective effect for children and adults is for the disseminated osteomyelitic form.²⁵⁴ The role of repeated BCG immunization to increase immunity^{159,254,302,330} to *M. ulcerans* infection is unclear. Using a recombinant BCG vaccine encoding an *M. ulcerans* mycolyl transferase, has been effective in murine models.¹²⁴ One *M. ulcerans*-specific vaccine target would be mycolactone, but this polyketide is poorly immunogenic, and antimycolactone antibodies are not detected in either cases or controls.⁵⁰ Mycobacterial heat shock protein (HSP) 45 is very immunogenic and protective in mouse models, but homology to a human HSP increases risk for autoimmune reactions.⁵⁷ In the absence of an effective vaccine, control strategies have focused on early detection and treatment, combined with physiotherapy to reduce scarring and functional limitations.³⁷⁵

Nocardia

99

Nada Harik • Richard F. Jacobs

Nocardia spp. are obligate aerobic bacilli that exist throughout the world as soil and dust saprotrophs. They are also found in salt and fresh water and rotting vegetable matter. These organisms are non-spore-forming, thin, branching, gram-positive, partially acid-fast, filamentous bacteria. Humans become infected with *Nocardia* by two primary routes: inhalation of contaminated airborne dust particles or traumatic implantation of the bacterium into subcutaneous tissue. Pulmonary disease is the form of nocardiosis recognized most commonly in the United States.⁵ The pulmonary event may be subclinical or transient, or it may provoke an acute or chronic process mimicking staphylococcal or fungal pneumonia, tuberculosis, or carcinoma. Hematogenous dissemination may occur, especially in immunocompromised hosts. The central nervous system (CNS) is the most common site of dissemination, with involvement manifested most often as a brain abscess. Cutaneous nocardiosis may be acute, subacute, or chronic (mycetoma). This form of disease is seen predominantly in immunocompetent hosts, with *Nocardia brasiliensis* being the agent identified most frequently.⁵⁰

In 1888, Nocard, a veterinarian, noted an aerobic actinomycete in bovine farcy, a chronic wasting disease in cattle characterized by pulmonary abscesses and draining cutaneous sinus tracts. H.L. Eppinger first described human disease in 1890. The earliest pediatric case was documented in 1895 in a boy with pulmonary and subcutaneous infection.⁸

ORGANISM

Nocardia spp. are included among the aerobic actinomycetes. They are gram-positive bacteria that are filamentous and branched and grow more slowly than other aerobic and facultatively anaerobic bacteria. They commonly produce a fungus-like mycelium that fragments or breaks up into rod-shaped and short coccoid forms. *Nocardia* spp. grow slowly on a variety of simple media (e.g., blood agar and brain-heart infusion agar); addition of carbon dioxide (10%) promotes more rapid growth. The organisms are inhibited by antibiotics and antifungal agents, so media containing such agents do not support the growth of *Nocardia*. Because of their growth on commonly used fungal media (e.g., Sabouraud dextrose agar) and on some mycobacterial media (e.g., Löwenstein-Jensen medium), many *Nocardia* samples may be misdirected to the mycology or mycobacteriology section of clinical laboratories for identification.

Nocardia spp. grow best at temperatures of 25°C to 45°C (77°F–113°F); growth at higher temperatures may be used for differentiation. In pure culture, small, chalky white, heaped, wrinkled, or verrucous colonies appear in 3 to 5 days. Mature colonies usually are light orange and have a velvety appearance caused by the production of rudimentary aerial mycelia. They have the odor of a musty basement or freshly turned soil. Detection of colonies from clinical specimens, such as respiratory secretions, may require 2 to 4 weeks. In mixed culture, rapidly growing bacteria may obscure small *Nocardia* colonies. Use of modified Thayer-Martin medium may enhance recovery.

Gram stain of a portion of a colony shows delicate, branching filaments no more than 1 µm in diameter. The filaments may fragment and produce bacillary or coccoid forms. Many *Nocardia* spp. are partially acid-fast (i.e., in contrast to *Mycobacterium* spp., they retain fuchsin less tenaciously). A modified Ziehl-Neelsen or Kinyoun stain that decolorizes with 1% sulfuric acid instead of the more active acid alcohol is best for showing beaded acid-fast *Nocardia* in clinical specimens. Acid-fastness is characteristic of *Nocardia* in tissue or primary colony isolates but is lost quickly on subculture; not all pathogenic strains of *Nocardia* are acid-fast.⁹ *N. asteroides* often survives the *N*-acetylcysteine digestion procedure (without sodium hydroxide) performed on sputum or bronchial washings; however, some positive sputum specimens may be rendered falsely negative.⁵⁸ Cultures of sputum and bronchial washings for isolation of *Nocardia* should be performed before and after the digestion procedure. Grocott's methenamine silver histochemical stain (GMS) can be used to detect *Nocardia* spp. in tissue specimens.

In the past, microscopic and colonial morphology, biochemical tests, chemotaxonomic methods, or antimicrobial susceptibility patterns were used to speciate *Nocardia*. 16S rRNA gene sequencing, multilocus sequence analysis, and polymerase chain reaction (PCR) restriction fragment length polymorphism (RFLP) analysis are the current methods most frequently used for speciation; use of these molecular techniques has resulted in changes in the nomenclature of *Nocardia* spp.¹⁴ Analyzing *Nocardia* spp. with molecular techniques has demonstrated that many species were previously misidentified using conventional techniques.⁵² Utilizing matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF) with custom databases for the identification of *Nocardia* spp. is promising.^{16,90}

More than 30 species of *Nocardia* of human clinical significance have been identified.¹⁴ Formerly, the term *Nocardia asteroides* complex was used to account for the heterogeneity in antimicrobial resistance patterns seen among *N. asteroides*. Detailed molecular analyses and susceptibility testing have established clearly that *N. asteroides* complex represented many different *Nocardia* spp.¹⁴ Various previously unrecognized *Nocardia* spp. have recently been reported to cause infection in humans.^{25,33,63} However, the most medically important species of *Nocardia* remain: *N. asteroides*, *Nocardia abscessus*, *Nocardia brasiliensis*, *Nocardia farcinica*, *Nocardia brevicatena/paucivorans* complex, *Nocardia nova* complex, *Nocardia otitidiscaviarum* complex, *Nocardia pseudobrasiliensis*, and *Nocardia transvalensis* complex.

EPIDEMIOLOGY, TRANSMISSION, AND PATHOGENESIS

Nocardia spp. can occasionally contaminate skin or colonize the upper respiratory tract.^{30,66,78} Bronchial obstruction and/or decreased bronchociliary clearance predisposes to colonization.⁶⁶ The importance of *Nocardia* spp. isolated in the sputum of individuals with cystic fibrosis

Keywords:

remains uncertain.^{65,70} The presence of signs and symptoms that correlate with nocardiosis can help ascertain the clinical significance of a positive *Nocardia* culture.

Most infections occur in the lungs, via inhalation.⁵ The second most common site of infection is the CNS.⁵ Although nocardiosis occurs in immunocompetent individuals, approximately 70% of patients are immunosuppressed by medications or underlying disease.⁵ The typical patient has compromised cellular immunity (secondary to steroids, organ transplantation, hematopoietic stem cell transplant, cytotoxic chemotherapy, chronic granulomatous disease, chronic alcoholism, diabetes mellitus, or human immunodeficiency virus [HIV] infection). Nocardiosis also is seen more commonly in patients with a history of surgery or trauma.⁵⁵ The risk of acquiring infection is increased in patients with chronic pulmonary disease and in any patient who is receiving long-term corticosteroid treatment. Person-to-person communicability has not been a problem. Historically the incidence of nocardiosis in the United States has been estimated to be approximately 500 to 1000 new cases per year.^{5,6} However, this number most likely is an underrepresentation, given the marked increase in the number of immunocompromised individuals. In addition, nocardial infections can be difficult to recognize, resulting in underestimation of the true incidence of nocardiosis. Presumed nosocomial nocardiosis has been reported.

Nocardiosis has been diagnosed in individuals of all ages (4 weeks to 83 years of age). Except in cases of cutaneous nocardiosis, almost all patients have one or more severe underlying diseases (e.g., lupus erythematosus, asthma, glomerulonephritis, ulcerative colitis, bronchiectasis, tuberculosis, rheumatoid arthritis, diabetes mellitus, or sarcoidosis) and/or are immunocompromised. Patients with lymphoreticular neoplasms and transplant recipients seem to be particularly at risk. The incidence of nocardiosis varies among transplant recipients with lung transplant recipients having the highest incidence.⁴⁸ In a literature review of nocardiosis in transplant recipients, the median time to infection was 7.5 months after hematopoietic stem cell transplantation and 21 months after solid organ transplantation.⁴⁸ Anti-tumor necrosis factor therapy (with infliximab, etanercept, and adalimumab) has been associated with the development of nocardial infection.^{1,2,83,88} This catalase-positive organism is one of the five main pathogens seen in children with chronic granulomatous disease and can cause severe infection.³⁶ Although *Nocardia* is not a surveillance organism for acquired immunodeficiency syndrome (AIDS), patients with HIV may contract nocardiosis.³⁷ In a review of all cases ($n = 25$) of nocardiosis at an urban adult teaching hospital from 1999 to 2004, 76% of patients with nocardiosis also were infected with HIV; all had CD4 counts less than 100 cells/mm³.¹⁷

Cutaneous nocardiosis usually is an infection of immunocompetent hosts. *N. brasiliensis* is isolated from approximately 80% of cases of primary cutaneous or subcutaneous nocardiosis.⁶⁸ Traumatic implantation of *Nocardia* into deep subcutaneous tissue may result in an indolent condition termed *actinomycotic mycetoma* (to distinguish it from the eumycotic mycetomas caused by true fungi).⁶¹ Mycetoma is a chronic, progressive infection that can extend to underlying bone. Actinomycotic mycetomas usually involve the lower extremities or hands and typically are caused by *Actinomyces* spp., non-acid-fast aerobic actinomycetes, or *Streptomyces* spp. Actinomycotic mycetomas caused by *Nocardia* frequently involve the chest and back. Mycetomas, the cause of which may be *N. brasiliensis*, have been described in Mexican and South American field workers. *N. brasiliensis* also has been documented as an opportunistic pathogen prevalent in Florida, with a predilection for diabetics.⁷³

In addition to the classic mycetoma, traumatic introduction of *Nocardia* spp. from soil may result in wound infections that occur after a more acute or subacute course. The organism can be introduced into the skin by tick⁴⁹ and other insect bites^{57,59} or by a cat scratch^{28,67} and result in cellulitis, pustules, or pyoderma; these conditions occasionally disseminate in immunocompromised individuals.^{39,40} Posttraumatic endophthalmitis,²⁹ necrotizing fasciitis,⁵¹ and poststernotomy mediastinitis^{79,91} have been described.

N. farcinica is a medically important pathogen.^{71,87} In a series of 200 cases of *Nocardia* infection reported by Wallace and associates,⁸⁷ the isolates designated *N. farcinica* were from patients with severe illness, 56% of whom had disseminated infections. *N. farcinica* isolates were characterized by increased resistance to antimicrobials, specifically third-generation

cephalosporins. Evidence from mouse models indicates that *N. farcinica* seems to be more virulent than are other *Nocardia* spp.²⁴ Because the various species of *Nocardia* seem to have different pathogenicities, determination of the infecting species of *Nocardia* is important.

In a retrospective review of cases of pediatric nocardiosis admitted to Arkansas Children's Hospital, five children with nocardiosis were identified from more than 100,000 admissions in a 10-year period. Four of the five patients had received a transplant within the previous year. Three of these patients had pulmonary disease caused by *N. asteroides*, and one transplant recipient had skin involvement with *N. brasiliensis* at a central venous line site. One immunocompetent 5-year-old boy contracted CNS infection caused by *N. asteroides* 2 months after incurring a penetrating brain injury.³⁴

The immune response to *Nocardia* is multifaceted.⁵ Neutrophils are mobilized to the site of infection and are the predominant cell type found in lesions. Neutrophils only inhibit the organisms, however, and limit the spread of infection until an adequate cell-mediated immune response develops or effective antimicrobial agents are administered. Immune T cells are vital in clearing *Nocardia* from the lung and preventing dissemination; many predisposing conditions for nocardiosis involve inadequate cell-mediated immunity. Activated macrophages induce cytotoxic T cells effective against *N. asteroides*. *Nocardia* may survive inside neutrophils and macrophages by inhibiting phagosome-lysosome fusion and production of catalase and superoxide dismutase, which inactivate the myeloperoxidase system. *Nocardia* organisms exhibit a differential ability to evade phagosome-lysosome fusion that depends on their state of growth, possibly related to specific cell wall mycolic acids detected only in log-phase cells.⁷ Differential cell wall characteristics also may influence the ability of *Nocardia* organisms to exhibit specific organ tropism (e.g., the brain).¹⁰ Antibody may play a role in host defense through enhancement of macrophage activities. Although antecedent conditions of nocardiosis frequently involve dysfunctional cellular immunity, other important preconditions include neutrophil disorders (chronic granulomatous disease) and immunoglobulin disorders.

PATHOLOGY

The lesions of nocardiosis are suppurative, whether in the lung or in subcutaneous tissue, and they involve primarily proliferation of neutrophils rather than formation of granulomas. Pulmonary nocardiosis in immunocompetent patients often resembles pulmonary actinomycosis in that it results in a chronic localized pneumonia that often abuts the pleura.³⁵ Indolent progressive fibrosis resembling fibronodular tuberculosis may occur. Pulmonary nocardiosis is more aggressive in immunocompromised patients and is manifested as multifocal necrotizing pneumonia with confluent abscess formation. *Nocardia* spp. tend to invade the pleura and chest wall, with tissue planes disregarded in the process. Little evidence of encapsulation is characteristic of all organs invaded and probably accounts for the ready dissemination of organisms from the initial pulmonary focus.

Nocardia spp. appear as delicate, beaded, branching filaments in tissue stained with Gram stain or modified acid-fast stain (Fig. 99.1). *Nocardia* spp. are invisible in hematoxylin and eosin preparations and in sections stained with periodic acid-Schiff for fungi. GMS preparations sometimes detect tissue organisms; overstaining with silver enhances visualization.

CLINICAL MANIFESTATIONS

The most common manifestation of nocardiosis (>40% of all cases) in the United States is pulmonary disease in a patient with underlying immunosuppression.^{22,62,66} Infection may remain localized to the lung or may disseminate hematogenously to the CNS and skin and, more rarely, to almost any organ in the body. In high-risk patients, the diagnosis should be suspected when CNS manifestations, particularly signs of a brain mass, abscess, or soft tissue swelling, develop in conjunction with a current or recent subacute or chronic pulmonary infection. Although sulfonamides are the most effective drugs for treatment of nocardiosis, invasive infections have been described in immunocompromised individuals receiving oral trimethoprim-sulfamethoxazole (TMP-SMX) as prophylaxis for *Pneumocystis jirovecii* pneumonia^{19,86} and in patients with chronic granulomatous disease receiving TMP-SMX prophylaxis.⁷⁴

FIG. 99.1 Appearance of *Nocardia asteroides* and *Nocardia brasiliensis* (arrows) in a properly decolorized acid-fast smear. Organisms appear as fragmented bacilli with stain concentrated in a beaded fashion along portions of the filaments (×160).

Clinical manifestations of pulmonary nocardiosis are not specific and include anorexia, weight loss, productive cough, pleural pain, dyspnea, and, occasionally, hemoptysis.²² Therefore, diagnosis of pulmonary nocardiosis is often delayed. In a recent study from China of adults with pulmonary nocardiosis, the median time to diagnosis was 25 days.¹⁸ Untreated pulmonary nocardiosis usually runs a chronic course, similar to that of tuberculosis, but it also may clear spontaneously and obscure the source of subsequent metastatic infection. The diverse clinical and radiographic manifestations, including acute bronchopneumonia, lobar pneumonia or necrotizing pneumonia with single or multiple abscesses, and pleural empyema, may mimic more common pulmonary infections, such as mycobacterial, staphylococcal, and fungal pneumonia. For example, common computed tomography (CT) findings of pulmonary nocardiosis include solitary or more often multiple lung nodules and lung consolidation with or without cavitation that are nonspecific.⁴¹ Pleural involvement (i.e., thickening or effusion) and chest wall extension are seen less commonly on CT.⁴¹ Normal hosts or patients with only slightly impaired host defenses may have only mild respiratory tract symptoms of several months' duration.²⁶

The CNS is the most common secondary site of infection, and such infection occurs in approximately one-third of patients.⁵ Most experts recommend performing routine cranial CT for patients with pulmonary nocardiosis even when they are asymptomatic because of the frequency of involvement of the CNS. Brain abscesses are the most common manifestation; meningitis is reported less frequently.^{4,12,19} In a literature review of 84 cases of CNS nocardiosis from 2000 to 2012, the most common signs and symptoms of infection were: focal neurologic abnormalities (51%), headache (45%), fever (40%), altered mental status (36%), seizures (28%), visual changes (21%), and nausea/vomiting (21%).⁴

Traumatic inoculation may result in localized disease manifested as cellulitis, mycetoma, subcutaneous abscess, or a lymphocutaneous syndrome in which one or more cutaneous nodules are associated with regional adenopathy or suppurative lymphadenitis.⁴⁷ Lymphocutaneous nocardiosis is clinically indistinguishable from sporotrichosis. Over a 5-year period, 31 cases of localized cutaneous nocardiosis with *N. brasiliensis* were identified in immunocompetent children in South Texas.²⁸ *Nocardia* spp. may cause cervicofacial disease and cervical adenitis in children.⁴⁶ Cutaneous nocardiosis can be mistaken for tularemia, mycobacterial infection, sporotrichosis, or superficial cellulitis due to *S. pyogenes* or *S. aureus*.

Other reported clinical manifestations of nocardiosis include tracheitis, peritonitis, iliopsoas abscess, hematogenous endophthalmitis, keratitis, endocarditis, mediastinitis, necrotizing fasciitis, septic arthritis, ventriculitis and choroid plexitis, sinusitis/orbital cellulitis, and osteomyelitis.^{22,42,45,51,56,75}

Bacteremic nocardiosis is reported rarely and usually is associated with endovascular foreign bodies in patients receiving long-term steroid therapy.⁴⁴ Catheter-associated *Nocardia* bacteremia also has been reported in a child with acute lymphoblastic leukemia (ALL) on maintenance chemotherapy.⁸⁹ In a report of six cases of central venous catheter-related *Nocardia* bacteremia, four cases were in children 18 years or younger.²⁷ All six patients received antibiotic therapy; the catheter was retained in three of the six. Relapse occurred in one of the three patients in whom the catheter was not removed.²⁷

DIAGNOSIS

The diagnosis of nocardiosis is established in one-third of cases by sputum analysis and culture. Humoral methods used to diagnose nocardiosis generally lack specificity because of the high degree of serologic cross reactivity that occurs among *Nocardia* spp. and between *Mycobacterium* and *Streptomyces* spp.¹¹ The decreased sensitivity for detection of an antibody response in immunocompromised individuals is also likely a limitation of serologic testing. It is important to notify the laboratory when nocardial infection is suspected so that steps can be taken to optimize its recognition and recovery. Although *Nocardia* colonies usually are evident by 3 to 5 days after culture, prolonged incubation may be necessary.

Bronchoalveolar lavage or lung biopsy may be required to establish the diagnosis. Although these procedures are invasive, given the overlap in symptoms with other infectious and neoplastic processes and potential for rapid progression of disease, bronchoalveolar lavage or lung biopsy should be considered early in immunodeficient patients to establish a definitive diagnosis. The demonstration of tissue invasion confirms active infection.

Tentative species identification of most *Nocardia* can be made by biochemical methods, chemotaxonomic methods, or antimicrobial susceptibility patterns. However, only *N. brasiliensis*, *N. farcinica*, and *N. pseudobrasiliensis* can be identified reliably by these methods.¹⁴ Molecular confirmation (e.g., DNA probes, PCR and PCR-RFLP molecular analyses, DNA sequencing, pyrosequencing, and ribotyping) of species identification is the method of choice. Molecular testing by hsp 65 PCR and 16S restriction enzyme analysis identifies more than 90% of currently recognized clinical species.¹⁴ PCR assays for identifying *Nocardia* spp. are not commercially available. Accurate identification of *Nocardia* spp. by MALDI-TOF with custom databases has been reported.^{16,90}

TREATMENT AND PROGNOSIS

Sulfonamides have been the best-studied drugs for the treatment of nocardiosis.^{69,74,85} In the United States, TMP-SMX, the only intravenous sulfonamide formulation available, has been the agent of choice for treatment of nocardiosis. TMP-SMX has been used successfully at doses of 15 mg/kg per day of TMP and 75 mg/kg per day of SMX, either parenterally or orally.^{74,82,84} Few cases have been reported of failure of TMP-SMX therapy for the treatment of nocardiosis.^{3,31,60,76} TMP-SMX resistance among *Nocardia* spp. has been documented. However, a study of sulfonamide resistance in isolates of *Nocardia* spp. from six major laboratories across the United States from 2005 and 2011 showed only 2% resistance to TMP-SMX or sulfamethoxazole.¹³ *N. farcinica* and *N. otitidiscaviarum* isolates are reported to have higher rates of resistance to TMP-SMX.^{38,80,81} However, in a recent study of 22 *N. farcinica* clinical isolates, 100% were susceptible to TMP-SMX (94% were resistant to ceftriaxone).⁴³ The 2011 Clinical and Laboratory Standards Institute document on susceptibility testing of mycobacteria and other aerobic actinomycetes recommends that all clinically significant isolates of *Nocardia* spp. be tested for susceptibility to multiple antimicrobial agents.²⁰ No published prospective clinical trials have correlated in vitro susceptibilities with clinical outcome for nocardiosis. Susceptibility testing is the best available guide for selecting appropriate combination therapy and alternative therapies if sulfonamides fail or cannot be given because of patient intolerance or allergy.

No prospective randomized trials have established the optimal antimicrobial therapy for nocardiosis. Recommended antimicrobial therapy regimens are based on efficacy in animal models of nocardiosis,

in vitro susceptibility and synergy testing, and retrospective clinical reviews and clinical case reports.¹⁴

TMP-SMX as a single agent usually is sufficient for patients with cutaneous nocardiosis. Many infectious disease specialists administer empiric combination drug therapy, consisting of TMP-SMX, amikacin, and a carbapenem or third-generation cephalosporin, for patients with severe disease, CNS nocardiosis, disseminated nocardiosis, and for immunosuppressed patients because of documented treatment failure and mortality associated with sulfonamide monotherapy in those settings.^{53,58,76} Currently, no *Nocardia* spp. are resistant to amikacin and a β -lactam in vitro; the use of both (plus TMP-SMX) ensures that all clinical isolates would be susceptible to at least one other drug.¹⁴ Antimicrobial therapy can be narrowed to two agents when results of in vitro susceptibility testing become available. Since antimicrobial resistance patterns vary by species, clinical isolates identified initially as *Nocardia* should be speciated further using molecular techniques. Children allergic to sulfonamides can be treated with amikacin and a carbapenem or third-generation cephalosporin.

The oxazolidinone linezolid is the first antimicrobial shown to be active in vitro against all clinically important *Nocardia* spp.¹⁵ Linezolid, which is available for oral administration, has been used successfully to treat 11 patients with nocardiosis.^{37,57} In one study, linezolid-associated hematologic toxicity was seen in three of six patients.⁵⁷ Peripheral neuropathy has also been observed in individuals with nocardiosis treated with linezolid.³⁸ Myelosuppression occurs more commonly in individuals receiving linezolid for longer than 2 weeks. Therefore, the use of linezolid for nocardial infection is limited by the prolonged treatment required for nocardiosis.

Clinical experience with minocycline, the tetracycline with best in vitro activity against *Nocardia*, has been encouraging. Amoxicillin-clavulanic acid has been effective in treating infections with *N. brasiliensis*, commonly a β -lactamase producer.⁸⁴ However, a case of acquired resistance to β -lactamase inhibitor antibiotics has been reported.⁷⁷ Other species with susceptibility to amoxicillin-clavulanic acid include *N. abscessus* and *N. farcinica*, whereas isolates of the *N. nova* complex are ampicillin susceptible or intermediate but resistant to amoxicillin-clavulanic acid.¹⁴ Susceptibility of some *Nocardia* spp. to fluoroquinolones has been reported. In an in vitro study, gatifloxacin and moxifloxacin generally were more active than was ciprofloxacin against isolates of *Nocardia*, especially against isolates of *N. farcinica* and *N. brasiliensis*.¹⁴ A patient with disseminated *N. farcinica* nocardiosis initially treated with aspiration, TMP-SMX, and imipenem had recurrence of brain lesions after a change to monotherapy with moxifloxacin despite in vitro susceptibility to moxifloxacin.²³ Recently, a benzothiazinone (PBTZ169) was shown to have significant in vivo activity against *N. brasiliensis* in a murine model of cutaneous nocardiosis.³²

Clinical improvement typically is seen within 7 to 10 days after initiation of appropriate therapy.⁵⁵ Patients with unchanged or worsening symptoms after receiving 2 weeks of therapy should be reassessed thoroughly. Intravenous antibiotic therapy may be changed to an oral regimen after at least 3 to 6 weeks if clinical improvement is noted. The variable and chronic course of nocardiosis precludes determining precise therapeutic end points. Metastatic lesions can appear during or after an otherwise effective course of sulfonamide therapy with maintenance of the recommended 100- to 150- μ g/mL level in serum or plasma. Because the tendency for relapse or the late appearance of metastatic disease is a concern, therapy often is continued for many months. Patients with mycetomas may require 6 to 12 months of therapy; localized cutaneous nocardiosis usually is treated for 3 to 6 months. Therapy for 6 to 12 months is suggested for patients with serious infection. Therapy for 12 months is indicated for patients with CNS nocardiosis and for immunocompromised patients.⁵⁰ Immunosuppressive medications should be reduced, if possible, during treatment for nocardiosis. Patients with CNS disease should be monitored with serial neuroimaging studies. Patients with AIDS probably should be treated with suppressive therapy indefinitely.

Surgical drainage of abscesses is important because metastatic abscesses can appear in the face of adequate therapy until surgical drainage is achieved.³⁰ Select brain abscesses may respond to antimicrobial treatment without surgery.⁵⁴

Historically, the overall mortality rate for nocardiosis is 25% to 40%,^{64,66} with higher rates having been reported in immunocompromised hosts with disseminated nocardiosis.⁶ Factors associated with increased mortality rates in one patient series were treatment with corticosteroids or antineoplastic agents, underlying Cushing disease, disseminated disease involving two or more noncontiguous organs or the CNS, and the presence of symptoms for less than 3 weeks before initial evaluation.⁶⁴ However, recent studies in immunocompromised patients with nocardiosis have reported mortality rates of 0% to 20%.^{21,43,72}

CORYNEBACTERIUM

The genus *Corynebacterium* comprises a wide number of organisms possessing little pathogenic potential, with some notable exceptions. The most infamous member of this genus, *C. diphtheriae* (see Chapter 90), is a cause of a potentially lethal pharyngeal infection with systemic manifestations. *Corynebacterium jeikeium* (formerly *Corynebacterium* group JK) can be a major nosocomial agent of bacteremia and endocarditis; other species commonly are associated with infections in animals and rarely cause invasive infection in humans.^{85,125} For an exhaustive consideration of coryneform bacteria, the reader is referred to the review by Funke and colleagues.⁵¹

Bacteriology

Corynebacterium spp. derive their name from their clublike shape. Because of their resemblance to *C. diphtheriae*, they are included in the heterogeneous group of diphtheroids. Snapping division produces the angular and palisade arrangement of cells responsible for their characteristic gram-positive, “Chinese letters” microscopic appearance.²⁷ Organisms are facultatively anaerobic or aerobic and do not produce spores. They are nonmotile and catalase positive and contain mycolic acid in their cell walls. Clinically relevant species include *C. diphtheriae*, *C. jeikeium*, *C. pseudotuberculosis*, *C. xerosis*, *C. amycolatum*, *C. pseudodiphtheriticum*, *C. minutissimum*, *C. striatum*, *C. ulcerans*, and *C. urealyticum*. Species can be differentiated according to biochemical tests and fermentation of sugars.^{27,51,121}

Epidemiology

Corynebacterium spp. can be part of the normal skin and upper respiratory tract flora and commonly colonize hospitalized patients. Nosocomial acquisition of *C. jeikeium* has been characterized most completely. Thirty-five percent of hospitalized patients may be colonized with *C. jeikeium*, and the organism may be isolated at the time of admission.⁵³ The skin, groin, and rectum are common sites of recovery of organisms. Wounds and suppurative sites quickly become colonized.⁵³ Longer duration of hospitalization, receipt of broad-spectrum antimicrobial agents, and impaired skin integrity are risk factors for invasive infection. Hospital personnel caring for oncology patients have higher rates of hand colonization with pathogenic *Corynebacterium* spp. than do nurses caring for dermatology patients.⁶⁷ Transmission from patient to patient in the hospital environment can occur, and selective antibiotic pressure has been shown to augment colonization with *Corynebacterium* spp.^{83,99,167} Outbreaks of bacteremic infection have been reported in hematology wards,^{116,141} and DNA restriction fragment analysis and hybridization techniques have been used to document spread.^{83,113}

It has been shown by whole genome sequencing that *C. jeikeium* actually comprises four different genomospecies, two of which can be differentiated from the other two by conventional microbiologic methods. Clinical isolates generally do not match the type strains.¹²⁷

Pathophysiology

C. jeikeium and *C. urealyticum* are lipophilic, which may account for their ability to proliferate on skin that has a higher lipid content; organisms have been isolated from sebum-filled eccrine gland biopsy specimens in an adolescent with malignancy.⁷² Breach of the integrity of the skin is an important risk factor for acquisition of local infection and bacteremia with *Corynebacterium*. Intravascular catheters increase the risk for infection.¹¹⁹ Certain isolates of *C. pseudotuberculosis* and *C. ulcerans* can express diphtheria-like toxins,¹⁶⁵ which may confer virulence.

Some *Corynebacterium* spp., notably *C. jeikeium* and *C. urealyticum*, commonly show resistance to penicillins, cephalosporins, aminoglycosides, erythromycin, and tetracycline.^{38,53,85,99,106,121,139} Strains with a

significant DNA relationship to the *C. jeikeium*-type strain show penicillin resistance.¹²⁰ Resistant organisms have been noted to have significantly thickened cell walls compared with susceptible strains, but the functional importance of this feature is unknown.¹⁶

Clinical Manifestations

Systemic infections with *Corynebacterium* spp. generally are not clinically distinguishable from serious infections caused by other pathogens. Immunocompromised patients are at the highest risk for developing disease caused by *Corynebacterium*,^{63,124} but infections also have been described in neonates and immunocompromised older children.^{14,38,76} Risk factors include male gender, neutropenia, broad-spectrum antibiotic exposure, and prolonged hospital stay.^{116,141} Catalase production may be responsible for the rare infection with non-JK *Corynebacterium* spp. in children with chronic granulomatous disease.⁷⁶ *Corynebacterium* spp. are responsible for approximately 9% of early-onset and 4% of late-onset prosthetic valve endocarditis.¹⁶⁴

C. jeikeium is a pathogen of particular concern. In 1976, this agent first was described as a cause of serious infection in four patients, including an 11-year-old boy with a ventriculoatrial shunt.⁶³ The other three patients had hematologic malignancies and were neutropenic at the time of infection. Immunocompromised patients, particularly patients with leukemia, are vulnerable to bacteremia. These high-risk subjects may show a local inflammatory lesion at the site of infection or a disseminated, hemorrhagic, or necrotic papular exanthem.¹⁰⁹ Subcutaneous nodules also may be seen. *C. jeikeium* has been recovered from disseminated lesions in a 14-year-old boy with leukemia.⁷² A literature review of 83 neutropenic patients (nearly all adults) with *C. jeikeium* sepsis found the following risk factors for development of infection: presence of a central venous catheter, being male, profound and prolonged neutropenia, and exposure to multiple antibiotics. Skin lesions were reported in 48% of patients, and pulmonary infiltrates were found in 36% of patients. The overall case-fatality rate was 34%, but it was reduced to 5% in patients with recovery from neutropenia.¹⁵⁴

Infections with *C. jeikeium* also have been reported after trauma, ventriculoperitoneal shunting procedures,^{3,78} orthopedic procedures,²⁶ bone marrow aspiration,³⁸ and central venous catheter placement.³⁸ *C. jeikeium* now is recognized to be one of the most common causes of prosthetic valve endocarditis in adults.¹⁰⁶ Cutaneous findings of bacteremia so commonly observed in patients with cancer generally are absent in patients with endocarditis.³³ In a series of 38 patients with *C. jeikeium* endocarditis, 74% of patients had prosthetic valves. The mortality rate was 33% and was not altered by valve replacement surgery.¹⁰⁴ According to a newer study, cases of endocarditis caused by *C. jeikeium* are more likely to require valve replacement than are those caused by other *Corynebacterium* spp.¹² Exit-site infections in patients on continuous ambulatory peritoneal dialysis also may be caused by *Corynebacterium* spp.; in the largest series published to date, *C. striatum* caused almost twice as many of these infections as did *C. jeikeium*. Most infections are manageable without removal of the dialysis catheter.¹³⁰ A case of malignant otitis externa that led to osteomyelitis of several skull bones and an epidural abscess which grew *C. jeikeium* along with *C. xerosis* and *Enterococcus faecalis* has been reported.⁸⁶

Although primarily a pathogen in farm animals, *C. pseudotuberculosis* can cause localized suppurative granulomatous lymphadenitis in humans^{85,103}; almost all cases are associated with animal contact, particularly sheep and goats.⁵⁴ Presentation and histology may mimic the much more common cat-scratch disease, and Gram stain and culture are required to differentiate the two entities.⁸⁵ Most cases have been reported from Australia.¹¹¹ The complete genome of an isolate

Abstract

The gram-positive rods encompass a vast number of species. They are widespread in the environment and are part of the normal flora of animals and humans. The focus of this chapter is on gram-positive bacilli seldom encountered as pathogens in healthy individuals. Many of these organisms show increasing prominence as causes of disease in immunocompromised patients. Bacteria from the genera *Corynebacterium* (other than *Corynebacterium diphtheriae*) and *Rhodococcus* are discussed.

taken from a 12-year-old girl with suppurative lymphadenitis has been sequenced.¹⁵²

C. xerosis has been reported as a rare cause of endocarditis, arthritis, and ventriculoperitoneal shunt infection.^{7,17} Most individuals with endocarditis have a prosthetic heart valve.^{42,89} In one case an implantable cardioversion device became infected with the organism.⁹³ *C. xerosis* also can be a cause of eye infections in patients with superficial corneal foreign bodies; in one study of 101 patients, *C. xerosis* caused three of 15 culture-positive cases.⁹⁰ It also is an extremely rare cause of post-LASIK (laser-assisted in-situ keratomileusis) infectious keratitis.³⁷ Using chemical testing and molecular genetic investigation, Funke and colleagues⁵⁰ showed that many isolates tentatively identified as *C. xerosis* are actually *C. amycolatum*. *C. amycolatum* is much more likely to be multidrug-resistant than *C. xerosis*.⁵¹ *C. amycolatum* is a comparatively common cause of bacteremia in children with cancer; of 12 cases of corynebacterial bacteremia reported from St. Jude Children's Research Hospital, three were caused by this species. In contrast to reports in adults, corynebacterial bacteremia in children usually started in the outpatient setting, happened in patients who were nonneutropenic, occurred relatively late in the course of cancer therapy, and had a relatively benign outcome.¹ In adults with cancer, *C. amycolatum* was often recovered from the upper urinary or lower respiratory tracts or found in surgical wounds or as an infection of ulcerating tumors.⁹⁶ It is generally seen in adults with solid tumors rather than hematologic malignancy.⁹⁶ A case of fatal sepsis in a premature neonate caused by *C. amycolatum* has been reported.¹⁴

C. pseudodiphtheriticum, a commensal of the oropharynx, can cause pneumonia, bronchitis, or tracheitis.^{2,28,31} Lung disease usually occurs in the context of underlying cardiopulmonary pathology or immunocompromise.⁶¹ Onset typically is acute, but fever may be noticeably absent.⁹¹ One cystic fibrosis center in France reported that 10 children had exacerbations that appeared to be related to respiratory tract infection with *C. pseudodiphtheriticum*; matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry was used to identify the isolates.¹⁵ At least 18 cases of *C. pseudodiphtheriticum* endocarditis, including three infections in children with congenital heart disease, have been reported.¹⁰⁵ Infection of allograft material is a common finding; native heart valves may be involved but usually in the context of preexisting lesions or intravenous drug abuse. In adults, endocarditis due to *C. pseudodiphtheriticum* has a predilection for men who have had a previous prosthetic valve replacement; infection with toxigenic strains appears to have a higher mortality rate.¹² Three cases of exudative pharyngitis with a pseudomembrane mimicking diphtheria, including one in a 4-year-old girl from Arkansas, have been reported to be caused by *C. pseudodiphtheriticum*.⁷¹ In one case, a surface swab from a draining wound after arthroscopy was reported to harbor "normal skin flora" but joint fluid grew the same organism, which was finally identified as *C. pseudodiphtheriticum*. Treatment resulted in resolution of symptoms of septic arthritis.⁷⁷ Patients who are immunocompromised and have corneal epithelial defects can get severe eye infections with this organism.⁸⁴ Rarely, ulcerative skin lesions have been described due to *C. pseudodiphtheriticum*.²²

C. minutissimum traditionally has been regarded as the cause of the mild cutaneous disease erythrasma, which is characterized by scaly, pruritic red-brown patches, usually occurring in the axilla, groin, or between the toes. Although *C. minutissimum* may play a role, erythrasma probably is a polymicrobial process.⁵¹ It may also be a secondary infection in patients with intertrigo.⁷⁴ *C. minutissimum* is recognized as a rare nosocomial infectious complication of malignancy and dialysis and has been implicated in a case of pyelonephritis in an 8-month-old infant with posterior urethral valves.³⁰ An adult who developed native-valve endocarditis caused by *C. minutissimum* has been reported.⁶ Bacteremia and meningitis due to this organism has been described in a patient with sickle-cell disease with an intravenously implanted right subclavian port.³²

C. striatum has been recovered from purulent sputum of hospitalized patients and from infected central venous catheter sites.^{132,160} It also is a cause of exit-site infections in patients on long-term ambulatory peritoneal dialysis.¹³⁰ It has been reported as a cause of fatal pulmonary infection and endocarditis.^{83,95,125} *C. striatum* was responsible for a

nosocomial outbreak among 14 patients over a 12-month period in a surgical intensive care unit. Endotracheal intubation for longer than 24 hours was the only risk factor found to predispose to infection.¹⁹ A second intensive care unit outbreak was reported from Italy; in this series, one of the patients was a 16-year-old admitted for severe trauma that resulted in having a sepsis-like picture and three blood cultures positive for *C. striatum*. Despite therapy with teicoplanin and meropenem, the patient died.⁶⁹ *C. striatum* also has been reported as a cause of meningitis and ventriculoperitoneal shunt infections.^{68,161} Several cases of septic arthritis have been reported.^{45, 131,156}

C. ulcerans derives its name from its association with ulcerative pharyngitis. Although it is more commonly a pathogen of nonhuman primates,¹¹⁰ infection can occur in humans after contact with an animal or consumption of contaminated raw milk.^{11,34} Toxigenic strains of *C. ulcerans* can produce a syndrome indistinguishable from that caused by toxigenic *C. diphtheriae*.^{23,149} The toxin has a different DNA and amino acid sequence from that of *C. diphtheriae*,¹³⁶ and is apparently carried by a different prophage.¹³⁴ In the United Kingdom, domestic *C. ulcerans* is now a more common cause of diphtheria than *C. diphtheriae*.¹⁵⁹ Cases in the United States are decidedly rare; the case of an 80-year-old man in Idaho reported in 2010 was the first case in 5 years.²⁴ Skin lesions that exactly mimic cutaneous diphtheria, caused by diphtheria toxin-secreting strains of *C. ulcerans*, also have been reported.¹⁵⁸

C. urealyticum (formerly *Corynebacterium* group D2) is a cause of alkaline-encrusted cystitis and pyelitis, primarily in the elderly.^{44,139} A case series of four children with encrusted cystitis and pyelitis has been published. The mean age was 9 years (range, 4–13 years). Treatment was with prolonged antibiotics and endoscopic debulking. Cure was effected in three of the four patients; the other patient was a renal transplant recipient who lost the graft.¹⁰² A prospective study of renal transplant recipients suggested that it is likely an underdiagnosed cause of obstructive uropathy in this group of patients; risk factors for infection were receipt of antibiotics in the previous month, nephrostomy, and skin colonization with the organism.⁸⁸ Routine urine culture may miss the organism; it may grow with prolonged incubation of sheep's blood agar.¹³⁵ It is associated less commonly with infection at other sites and with bacteremia.¹³⁸ An 8-year-old boy with chemotherapy-induced neutropenia and a necrotic soft tissue infection of the scrotum caused by *C. urealyticum* has been reported.¹²⁶ Cure of bacteremia in a patient with obstruction due to prostate cancer was not effected until his percutaneous nephrostomy tube was removed.²⁵

Diagnosis

Diagnosis of *Corynebacterium* infection is based on isolation of the organism from clinical material. This organism commonly is accompanied by other pathogens. Similar to *Mycobacterium* and *Nocardia* spp., *Corynebacterium* organisms have mycolic acids in their cell wall. The chains are shorter, however, and the organisms are not acid fast. *Corynebacterium* spp. may be difficult to distinguish from some *Rhodococcus* spp.²⁷ Colonies of *C. jeikeium* may show a metallic sheen when grown on agar.⁶³ Growth of *C. jeikeium* is enhanced by the addition of lipids to the medium. Most *Corynebacterium* spp. can be differentiated quickly from each other by sugar fermentation, hydrolysis of urea, and reduction of nitrate.¹⁴⁸ Selective media containing kanamycin or trimethoprim-sulfamethoxazole have been useful in the recovery of multidrug-resistant strains of *Corynebacterium*.⁶² The API Coryne system version 2.0 correctly identified 162 of 178 (91%) isolates in one study.⁵ Polymerase chain reaction testing and MALDI-TOF spectrometry are quite accurate for specific identification at the species level, and are increasingly being used. Erythrasma usually is diagnosed by the typical coral red fluorescence under Wood lamp examination.

Treatment

Empirical therapy for infection must account for the frequency of infection with *C. jeikeium*, which often is multiresistant to antibiotics but is susceptible to vancomycin.⁵¹ In some series of immunocompromised patients, this organism is the most common *Corynebacterium* spp. encountered.^{140,163} Vancomycin is recommended for empirical therapy for suspected *Corynebacterium* infection until susceptibilities are known.

Treatment can be changed to a penicillin or cephalosporin, if appropriate. In vitro, *C. jeikeium* is sensitive to linezolid,⁵⁶ and most strains also are sensitive to quinupristin-dalfopristin¹²⁸ and daptomycin.⁵⁵ Treatment with daptomycin, however, has been associated with development of resistance in *C. striatum* strains during therapy.^{98,162} This phenomenon has also been replicated in vitro.⁹⁸ In one worrisome case, a man who had received two long courses of daptomycin for MRSA infection developed native valve endocarditis with a strain of *C. striatum* that was heteroresistant to daptomycin.¹⁵¹ A majority of strains is also sensitive to tigecycline, but experience with the antibiotic in childhood is sparse.⁴⁶ Linezolid is bacteriostatic against all species of *Corynebacterium*, and in vitro its activity is slower against *C. jeikeium* than it is against *C. striatum* and *C. amycolatum*.⁵⁶

Two-drug therapy generally is recommended for treatment of *Corynebacterium* endocarditis; for gentamicin-susceptible strains, penicillin-gentamicin combinations have been shown to be synergistic, regardless of whether the strains are susceptible to penicillin.¹⁰⁶ Rarely, resistance to vancomycin is encountered. A woman with prosthetic valve endocarditis caused by a vancomycin-resistant *Corynebacterium* spp. was treated successfully with imipenem and ciprofloxacin.¹⁰ Removal of infectious sources, such as central nervous system shunts and central venous catheters, may be required for cure. Scrupulous attention given to skin hygiene may reduce colonization of hospital personnel and the incidence of patient-to-patient transmission of pathogenic strains.^{40,116} Management of toxigenic *C. ulcerans* infection is identical to that for infection caused by toxigenic *C. diphtheriae*, including the use of antitoxin.¹⁴⁹ Erythrasma usually responds to treatment with a macrolide.

RHODOCOCCLUS

The genus *Rhodococcus* contains at least 15 species, of which *Rhodococcus equi* is the most clinically relevant to humans. Infections with other species are rare. Suppurative keratitis caused by *Rhodococcus ruber* after penetrating trauma has been described.⁸⁰ One case of bacteremia with *R. globerulus* was reported in a stem-cell transplant patient.¹¹⁷ *R. equi* derives its name from its role as a cause of pyogranulomatous pneumonia in young horses.¹¹⁴ It has assumed a prominent role as a cause of human pulmonary disease in immunocompromised patients, particularly in patients with acquired immunodeficiency syndrome (AIDS).^{43,64,132} For a comprehensive discussion of this organism, the reader is referred to the review by Cornish and Washington.²⁹

Bacteriology

R. equi is a catalase-positive, urease-positive, oxidase-negative, gram-positive rod. The organism assumes a more coccoid morphology in solid media and a more bacillary form in liquid media. Its cell wall contains mycolic acid, rendering it acid fast when grown on Lowenstein-Jensen media and stained with Kinyoun stain.⁵⁷

Epidemiology

R. equi is a soil organism, and its growth is enriched by the manure of herbivores. Despite the common occurrence of this pathogen as a cause of veterinary infections, exposure to animals apparently is not necessary for human infection to occur¹¹⁴; most reported human patients have not had farm or animal exposure.⁶⁴ Hospital outbreaks of infection associated with patient-to-patient transmission have not been reported. In a retrospective analysis of 24 cases of *R. equi* infection, however, six patients had shared a hospital room with a patient with *R. equi* pneumonia, raising the possibility of nosocomial transmission.⁸ Most patients diagnosed with *Rhodococcus* infection are immunocompromised; AIDS is the most common underlying diagnosis, but infection also has been reported in transplant patients⁹ and rarely in patients believed to be immunocompetent.¹⁵³ In one case, infective endocarditis with severe complications including subarachnoid hemorrhage and subdural hematoma was reported in a patient with a normal immune workup.⁹⁷ On the other hand, a chronic, nonhealing ulcerative lesion caused by *R. equi* in a man believed to be immunocompetent led to a diagnostic workup that proved the cause to be a CD8 deficit.³⁶

Chemotherapeutic agents such as fludarabine, which causes prolonged CD4 lymphocytopenia, can predispose to *R. equi* infection.⁵² Receipt

of high-dose corticosteroids¹²² and alemtuzumab (an anti-CD52 monoclonal antibody) have also been reported as antecedents of infection.¹⁰¹

Pathophysiology

The prominence of pulmonary infection suggests that the respiratory tract is a common portal of entry. After gaining access to the lower respiratory tract, organisms are taken up by alveolar macrophages; Mac-1 macrophage receptors and complement are required for binding.⁶⁵ The organism replicates within a modified phenotypic vacuole; pathogenicity is dependent upon a plasmid that prevents phagosome-lysosome fusion.¹⁵⁵ The appearance of pyogranulomatous lesions is consistent with the role of *R. equi* as an intracellular parasite containing mycolic acid, a possible virulence factor in the cell wall.^{58,115} Surface 15- and 17-kDa antigens expressed by an 85-kb plasmid seem to confer virulence in mice and foals,¹⁴³ and virulent strains seem to have an increased capacity for intracellular survival in macrophages.⁶⁶

Most *R. equi* isolates from patients with AIDS express either the 15- to 17-kDa antigens or a 20-kDa antigen that seems to confer intermediate virulence. Most isolates from patients without AIDS express none of these antigens, however.¹⁴⁴ Other factors may play a role in promoting *Rhodococcus* disease in humans.¹⁴⁵ Death of parasitized macrophages may release enzymes, which contribute further to tissue damage. In vitro, infected respiratory epithelial cells upregulate the production of IL-6 and IL-8.¹¹⁸ CD4⁺ lymphocytes are essential for pulmonary clearance of *R. equi* in a mouse model,⁷⁵ which may help to explain the high risk for infection associated with cellular immunodeficiency.

Clinical Manifestations

Infection typically manifests as a subacute pneumonia developing over several weeks. Symptoms such as cough and fever are common, but progression of disease may be silent. Although most infections currently occur in patients with AIDS, malignancy and transplantation¹⁶⁶ also pose risks. Pulmonary infection in children with leukemia has been described.^{4,100} Infection may be accompanied by other pathogens, particularly in patients with AIDS.

Pulmonary infection often is pleura based and associated with cavitation.⁶⁴ Empyema may occur as a complication. Computed tomography most frequently reveals pneumonia with cavitation, but other patterns, including ground-glass opacities, peribronchial nodules, and centrilobular nodules, may be seen.⁹² Lung tissue showing malakoplakia, an unusual-appearing granulomatous inflammation with aggregates of histiocytes that contain concentrically layered basophilic inclusions, should raise suspicion of the presence of *R. equi* infection.^{21,59,129}

Extrapulmonary disease is seen at diagnosis in 7% of patients with pneumonia.¹⁵⁷ Manifestations of infection include otitis/mastoiditis,^{4,70,87} abscesses,⁴⁷ osteomyelitis,^{18,48,108} meningitis,^{35,133} pericarditis,⁸² lymphadenitis,⁸² and endophthalmitis.⁴¹ The organism has been grown from a biopsy of a granulomatous skin lesion in an immunocompetent 7-year-old girl.⁹⁴ *R. equi* also has been reported as a cause of peritonitis in patients receiving long-term peritoneal dialysis.^{20,146} A case report of ventriculitis in a premature infant with a ventriculoperitoneal shunt has been reported.¹⁴²

Diagnosis

Diagnosis relies on isolation of *Rhodococcus* from clinical material. Although sputum specimens may be positive, bronchoalveolar lavage or lung biopsy may be required. Blood cultures may be positive in half or more of patients with AIDS and with focal pneumonic disease.¹⁵⁰ The physician should be alert to the possible coexistence of *R. equi* with other pathogens. In the laboratory, confusing this organism with *Corynebacterium*, acid-fast organisms, and other gram-positive coccobacilli has been shown to delay establishment of the diagnosis.³⁹ Positive findings on Gram stain and Kinyoun stain should be interpreted in the context of clinical information.¹³² Organisms appear salmon-pink when grown on blood agar and orange on Lowenstein-Jensen medium.¹³ Differentiating from acid-fast bacteria on smear sometimes can be difficult. Combined use of a siderophore detection medium, ethylene glycol degradation, and β -galactosidase activity may help differentiate

Rhodococcus from *Nocardia* and rapid-growing mycobacteria.⁴⁹ DNA restriction fragment analysis and ribotyping show promise in aiding the identification and tracking of *Rhodococcus* spp.⁸¹ An *R. equi*-specific polymerase chain reaction assay has been used to confirm infection in some cases in which identification was difficult.¹

Differentiation of *R. equi* from other species of the genus *Rhodococcus* can be difficult and may frequently be incorrect; 16S rRNA genome sequencing analysis sometimes identifies a different species of *Rhodococcus* from specimens originally signed out as *R. equi*.⁶⁰ Also, organisms of the genus *Dietzia* are often misidentified as *R. equi*.⁷⁹ In one study, only 7 of 15 clinical specimens originally called *R. equi* by the microbiology laboratory were actually *Rhodococcus* isolates; the 8 others were all members of the genus *Dietzia*.¹¹²

Treatment

Clinical isolates commonly are resistant to penicillins and cephalosporins. Even if susceptible in vitro, β -lactam antibiotics should be avoided because of rapid development of resistance.⁷³ Erythromycin, clarithromycin, azithromycin, clindamycin, rifampin, aminoglycosides, vancomycin, fluoroquinolones, and imipenem are active against *R. equi*.¹⁰⁷ Moxifloxacin is more active in vitro than is either ciprofloxacin or levofloxacin.¹²³ Synergy has been shown with various combinations of these agents. Including rifampin or azithromycin in a two-drug combination has been recommended because of penetrance of macrophages.^{13,137} Combinations of antibiotics that included vancomycin were found to be most effective in clearing infection in a mouse model.¹⁰⁷ The combination of levofloxacin or ciprofloxacin and azithromycin is sometimes successfully employed. Cure rates in adults with lung infection are approximately 60% when antibiotic therapy alone is employed but may reach 75% when combined with surgical resection of infected pulmonary tissue.⁶⁴ Surgery has not been shown to increase survival rates, however.⁸

Pediatric patients generally have fared better than adults, but most reported cases in children have been in non-AIDS patients.¹³ Relapse is a common occurrence, but the optimal duration of therapy to prevent relapse is unknown. For patients with AIDS, some authors recommend a minimum of 2 months of therapy followed by long-term suppressive therapy.⁷³ Relapse has been reported to occur at extrapulmonary sites in 13% of immunocompromised patients,¹⁵⁷ often without reappearance of pulmonary disease. Treatment of *R. equi* peritonitis in patients receiving peritoneal dialysis has been reported to be successful with

intraperitoneal imipenem or vancomycin for 14 days.^{20,147} Removal of the peritoneal dialysis catheter may be required for cure.

SUBSECTION IV Gram-Negative Bacilli

101

Citrobacter

Lawrence A. Ross • Randall G. Fisher

Citrobacter, a genus of enteric gram-negative rods closely related to *Salmonella*, has been increasingly associated with human disease. Although *Citrobacter* strains usually are not considered normal inhabitants of the intestinal tract of humans and animals,^{69,119} a study using 16S rDNA polymerase chain reaction (PCR) showed that normal newborns are colonized with these organisms by day 6 of life.⁷⁹ The impact of perinatal factors, such as Caesarean section, upon intestinal colonization with *Enterobacteriaceae*, including *Citrobacter* species, is of growing interest.¹⁰⁵ *Citrobacter* species are associated with a broad spectrum of clinical diseases, including urinary tract infections,^{9,31,50,61,64,69} osteomyelitis,⁶⁴ diarrhea,^{25,38,122} and invasive disease in the immunocompromised host.^{46,50,64,69} Further, *Citrobacter* species are identified as emerging nosocomial pathogens,⁵ including potential acquisition from contaminated transfusion products.^{44,26} As detailed in a review by Doran,²³

Citrobacter commonly is associated with sepsis, meningitis, and brain abscess in neonates.

BACTERIOLOGY

In 1931, Werkman and Gillen¹¹⁹ proposed the generic term *Citrobacter* for citrate-positive coli-aerogenes intermediates isolated from stool. This genus now includes 11 species, of which the most commonly identified are *Citrobacter freundii*, *Citrobacter koseri* (formerly *Citrobacter diversus*), and *Citrobacter farmeri* (formerly *Citrobacter amalonaticus*).¹⁰ Additional species are likely to be identified using advanced analytic methodology.¹⁸ *Citrobacter rodentium* induces inflammatory colitis in laboratory animals that is similar to that induced by pathogenic strains of *Escherichia coli*. Such research models have been useful for delineation

of the pathogenesis of microbial-mediated colonic inflammation.²⁰ *Citrobacter* are straight, facultatively anaerobic bacilli possessing peritrichous flagellae that confer motility. In addition to using citrate, these organisms hydrolyze urea and ferment glucose, with production of gas.¹⁰² They grow on ordinary media as gray, opaque, round colonies that produce a strong, fetid odor. In contrast to *Salmonella*, *Citrobacter* grows in the presence of potassium cyanide. Indole-negative strains that produce hydrogen sulfide are classified as *C. freundii*. Indole-positive, hydrogen sulfide-negative strains are differentiated by their ability to ferment malonate; *C. koseri* ferments malonate, whereas *C. farmeri* does not.³ Antigenic schemata have been developed to classify the O somatic antigens of *Citrobacter*^{33,37,122}; these antigens show cross reactivity with O antigens of other *Enterobacteriaceae*.

EPIDEMIOLOGY

Meningitis caused by *Citrobacter* was reported first in 1960, with two cases of *C. freundii*.⁴² In the decade from 1970 to 1979, 69 cases of *Citrobacter* meningitis were reported,³⁴ and 4% of neonatal meningitis cases reported in the First Neonatal Meningitis Cooperative Study Group were caused by *Citrobacter*.⁷⁴ *C. koseri* is the species usually isolated with meningitis; central nervous system infection caused by *C. freundii* occurs less commonly.^{23,34,92} Most cases in the United States are reported from southern states; biotype d or serotypes O2 and O1³⁴ are the most common isolates of *C. koseri* encountered.

Most cases of neonatal meningitis caused by this organism have been sporadic. The source of sporadic cases usually is unknown, but nine cases clearly have been documented to be vertically transmitted from mother to infant.²³ In addition, several well-documented nosocomial outbreaks of infection have been reported.^{27,31,33,63,80,91,122} The source usually is the gastrointestinal tract or hands of nursery staff. One cluster was associated with contaminated formula.¹¹² When *Citrobacter* is introduced into the neonatal nursery, colonization may exceed 79%.³³ Parry and associates⁸⁰ described a nursery outbreak in which 11 of 128 infants were colonized with *C. koseri* over an observation period of 3 months; two of the colonized infants developed meningitis. Additional colonization of neonates seemed to be eliminated by removal of a nurse with persistent hand carriage of the organism.

In another outbreak,¹²² introduction of *C. koseri* into the nursery was linked to an infant admitted with meningitis. Thirty-one percent of infants in the nursery subsequent to the index case were found to be colonized with *C. koseri* of the same serotype and biotype. A second infant from this study developed meningitis with the organism during the observation period. Umbilical colonization of infants in this cluster was more common than was rectal colonization, but rectal colonization was more persistent, lasting 4 months. Two nurses were found to have hand colonization with the organism, and the reintroduction of these bacteria into the nursery was linked to a pregnant nurse who had perineal cultures at delivery yielding the epidemic strain. She was implicated in the colonization of her own infant and three other neonates. Corresponding culture data from a reference hospital revealed an overall neonatal colonization rate with *Citrobacter* of 1% to 10% over a 5-year period, with no invasive disease. Of interest, a research study performed in very-low-birth-weight infants administered human recombinant lactoferrin developed altered fecal microbiomes, including increased colonization with *Citrobacter*; the relevance of this observation is unclear.¹⁰⁰

Although *Citrobacter* has been isolated increasingly from debilitated adult patients,^{120,97} particularly as a urinary tract,^{50,64,69,89} soft tissue,^{24,64,69} and bone⁶⁹ pathogen, *Citrobacter* infection in children is unusual after the first 2 months of life. One case of meningitis was reported in a teenager who lacked apparent risk factors or immunodeficiency.⁸⁷ In older children, *Citrobacter* spp. are more likely to cause opportunistic infections in immunocompromised hosts, including a recent association of *C. freundii* infections in patients with heterotaxy syndrome.¹⁵ *Citrobacter* are established etiologic agents of urinary tract infections in pediatric patients; one study showed *Citrobacter* spp. to be responsible for 37 (1.4%) urinary tract infections in children over a 3-year period.²⁹ One-quarter of infections were nosocomially acquired, and one-third occurred in children with urinary tract abnormalities. A more recent study from Kosovo of 299 children with urinary tract infections found

that *Citrobacter* spp. caused 5.4% of cases, making it the fourth most common cause.¹⁰⁴

PATHOPHYSIOLOGY

Citrobacter infrequently colonizes the intestinal tract and perineum of humans.⁵⁰ Vertical transmission of strains shown to be identical by DNA typing shows that the newborn can acquire colonization at the time of passage through the birth canal of a colonized mother.^{43,78} Onset of disease beyond the first week of life is related commonly to colonization of the infant in the nursery. As with other types of gram-negative neonatal meningitis, central nervous system infection results from bacteremia in a colonized infant, leading to seeding of the meninges.

The basis for the particular invasiveness of *Citrobacter* in the neonate and its propensity to cause multiple brain abscesses are largely unexplained. *Citrobacter* spp. possess the ability to invade, transcytose, and multiply within human brain microvascular endothelial cells in vitro.⁶ Additionally, in the neonatal rat model, after being taken up into macrophages, *C. koseri* is able to survive phagolysosomal fusion and replicate therein.¹¹³ Many strains of *C. koseri* seem to be able to produce brain pathologic processes in the mouse, but the degree of damage seems to be related to virulence of the strain and the age of the mouse.^{57,103} Differences in strains, related to the presence of an outer-membrane protein with a molecular weight of 32,000 kDa, have been associated with differences in brain histopathology in one infant rat model of *C. koseri* meningitis.⁵⁶ Strains isolated from cerebrospinal fluid of infants with meningitis more commonly possess this outer-membrane protein than do strains isolated from other body sites.⁵⁷ In the mouse model, early proinflammatory mediator release was dependent on MyDD88 (a signaling adapter of Toll-like receptor 4 [TL4]). MyDD88 knockout mice had enhanced mortality and elevated bacterial burdens versus wild-type mice.⁶⁵ In vitro, microglial cells respond with inflammation via TL4 and MyDD88.⁶⁶

In an immunocompromised patient, broad use of antimicrobial agents may produce selective pressure, leading to increased colonization with *Citrobacter*. Increased bacterial density combined with a blunted immune response may result in invasive disease. Some strains of *C. freundii* produce Shiga toxins (verotoxins) nearly identical to those produced by enterohemorrhagic strains of *Escherichia coli*.⁹⁸ At least one outbreak of gastroenteritis and the hemolytic-uremic syndrome caused by Shiga toxin-producing *C. freundii* has been reported.¹¹⁵ Investigation of pathogenesis and molecular correlates of colitis in murine models using *C. rodentium* have clarified the basis for intestinal defense and response to infection.⁹⁵

Citrobacter spp. contain type 3 fimbriae, which are vital to the production of biofilms.⁷⁷ The formation of biofilms in *Citrobacter* isolates is important in the pathogenesis of catheter-associated urinary tract infections.⁷⁷

CLINICAL MANIFESTATIONS

Citrobacter, similar to other neonatal pathogens, can cause early-onset and late-onset infection. In a review of 74 cases of neonatal meningitis caused by these bacteria, the mean age of onset reported for early disease was 7 days; 85% of patients were included in this group.³⁴ Fifteen percent of cases occurred after 3 weeks of age. Twenty-three (31%) of 74 patients were younger than 36 weeks of gestational age at birth, suggesting that preterm infants are at increased risk for acquisition of *Citrobacter* infection. Prematurity is even more common (71%) in cases that are proved to be vertically acquired.²³

Clinical signs and symptoms are typical of neonatal sepsis. Fever, lethargy, poor feeding, vomiting, irritability, bulging fontanelle, seizures, and jaundice are common presenting features. Umbilical infection and surgical manipulation of colonized umbilical stumps occasionally have preceded development of bacteremia and meningitis.⁸⁰ The white blood cell count may show leukocytosis or leukopenia. Cerebrospinal fluid findings are consistent with those of most types of neonatal bacterial meningitis and usually show polymorphonuclear cell elevation, elevated protein, and depressed glucose; gram-negative rods may be seen on smear. Although growing the organism in culture normally is not difficult,

in one reported case standard cultures were negative, but the organism was recovered by direct inoculation of cerebrospinal fluid into a BACTEC blood culture bottle.¹⁹ Of *Citrobacter* meningitis cases in which the results of blood cultures are reported, 80% document concurrent bacteremia.²³

Citrobacter is a particularly devastating cause of neonatal meningitis. The most common *Citrobacter* spp. causing neonatal meningitis is *C. koseri*, which accounts for more than 80% of the cases.²³ Central nervous system infection with this organism produces multiple brain abscesses with unusually high frequency.^{34,40,51,57,62} In the extensive reviews by Graham and Band³⁴ and by Doran,²³ three-quarters of *Citrobacter* meningitis cases resulted in intracerebral abscesses. By comparison, the incidence of abscess formation in non-*Citrobacter* gram-negative meningitis is reported to be as low as 10%.³⁴ The case-fatality rate for *Citrobacter* meningitis is approximately 30%, and at least three-quarters of surviving infants have neurologic sequelae, such as mental retardation, hemiparesis, seizures, and developmental delay.²³

The presence of brain abscess seems to contribute substantially to morbidity and mortality^{21,33,34}; however, a favorable outcome may be observed.¹ For unknown reasons, neonates with vertically acquired *Citrobacter* meningitis seem to be less likely to develop intracerebral abscesses.²³ At least four cases in which diffuse pneumocephalus developed in association with *Citrobacter* meningitis have been reported; in one, gas was noted to accumulate within the brain and in the anterior chamber of the eye, a condition known as *pneumosis oculi*.^{2,85,99} Rarely, *Citrobacter* infection in the neonatal period may lead to focal infection not involving the central nervous system. A case of septic arthritis and osteomyelitis of the shoulder in a 3-week-old infant has been reported.⁴⁵

In adults, *Citrobacter* is isolated most commonly from the urinary tract.^{50,64,69,89} In earlier studies, 5% to 12% of bacterial isolates from urinary tract infections in adult patients were *Citrobacter*.^{25,121} More recently, in a health maintenance organization, *Citrobacter* spp. accounted for only 0.8% of 4342 isolates from women with acute uncomplicated cystitis.³⁹ *Citrobacter* spp. are a similarly uncommon cause of urinary tract infection in children.²⁹ Sputum is the second most common clinical specimen to yield *Citrobacter* in adults⁵⁰; lung abscess,³⁰ pneumonia,^{64,69} bronchitis,⁴⁶ and septic arthritis⁶⁴ have been reported. *Citrobacter* is an occasional cause of bacteremia in hospitalized patients, accounting for approximately 0.5% of blood culture isolates.^{83,101} In one series, all 45 patients had at least one underlying disease, with malignancies (particularly intraabdominal tumors) and hepatobiliary stones being the most frequent coexisting conditions.¹⁰¹ Polymicrobial bacteremia occurred in one-third of patients. Bacteremia with *Citrobacter* has been observed in a recipient of haematopoietic stem cell transplantation with fever and neutropenia.¹¹⁷ In a series of six bacteremic patients who had *Citrobacter* species other than *freundii* or *koseri*, five of the six had associated intraabdominal infection; cancer and cirrhosis were the most common underlying diseases.⁶⁰

A broad spectrum of organ-specific infections caused by *Citrobacter* have been reported; these include liver abscess,⁵⁸ infective endocarditis,⁹⁰ spinal epidural abscess,⁵⁹ folliculitis,⁸⁸ and sinus disease complicated by orbital extension.⁶⁸

Gastrointestinal disease occasionally has been attributed to *Citrobacter*, but frequent isolation of this agent from normal stools often renders this diagnosis equivocal. This genus was implicated first in an outbreak of mild gastroenteritis by Barnes and Cherry⁸ in 1946, and an outbreak of watery diarrhea in a Virginia infant care unit included two infants in whom isolates of enterotoxin-liberating *Citrobacter* were obtained from the stool.³⁸ Some studies have found higher incidences of *Citrobacter* isolation from the stool of patients with enterocolitis syndrome than from stools of control patients.¹²² Shiga-toxin (verotoxin)-producing *C. freundii* isolated from organically grown parsley was associated with an outbreak of diarrhea and hemolytic-uremic syndrome in a daycare setting.¹¹⁵ *C. freundii* has been found as a cause of appendicitis in a healthy adult,⁶⁴ peritonitis in adults with liver disease or pancreatitis,⁶⁴ neutropenic colitis after chemotherapy for breast cancer,¹⁷ and meningitis in adults as a complication of neurosurgery.¹¹¹ A case of Meleney gangrene occurring after cesarean section delivery has been reported.¹¹⁰

A patient with diabetes developed necrotizing fasciitis caused by *C. freundii* associated with injury from a fish fin.¹⁶ Bone and soft tissue

infections occur^{11,35,106}; 3% of *Citrobacter* pathogens were isolated from joint or bone in one adult series.⁶⁴ One 53-year-old man developed infection 3 weeks after total hip arthroplasty, a condition normally expected to be caused by *S. aureus*.⁵² Eye infections, including keratitis,³² traumatic endophthalmitis,^{12,94} and endogenous endophthalmitis¹⁴ have been reported. *Citrobacter* has been identified as a pathogen in patients with dacryocystitis.⁴ A case of *C. freundii* pharyngitis complicated by retropharyngeal abscess and mediastinitis was cured by minimally invasive surgery and intravenous antibiotics.¹¹⁴

DIAGNOSIS

Biochemical characteristics of *C. koseri* include lack of hydrogen sulfide production on triple-sugar iron agar, negative Voges-Proskauer reaction, use of citrate, motility, production of indole, decarboxylation of ornithine but not lysine, and production of acid from adonitol.³ Identification of this organism as a pathogen in a nursery setting should heighten suspicion of its possible role in subsequent neonatal infections. *C. freundii* is indole negative and hydrogen sulfide positive, which differentiates it from *C. koseri*. *C. farmeri* differs from *C. koseri* because of the former's inability to ferment malonate. *C. freundii* and *C. farmeri* account for a significant portion of disease caused by *Citrobacter* in immunocompromised individuals and should be suspected particularly in this group of patients.⁴⁶ In some cases, *C. freundii* can be misidentified as *Cronobacter* spp. by commercial systems.²⁸

Infants with invasive *Citrobacter* disease present in a similar fashion to infants with sepsis and meningitis of other causes. Such infants should undergo a thorough evaluation, including blood and urine culture and cerebrospinal fluid studies. Emerging laboratory methods have facilitated more rapid identification of gram-negative isolates, as well as identifying the presence of antimicrobial-resistance factors.¹⁰⁷ Brain imaging studies should be obtained and when indicated, sequentially followed when the diagnosis of meningitis is established. Magnetic resonance imaging (MRI) is the most sensitive diagnostic tool for early identification of cerebritis and early abscess formation; however, computed tomography is the most common imaging evaluation performed. Ultrasound often is more feasible for an unstable neonate and may be nearly as sensitive in detecting abscesses.^{62,75,123} Serial imaging studies should be done because abscesses may develop during the first few weeks of illness. In cases in which the cerebrospinal fluid cultures are negative because of prior antimicrobial therapy, surgical aspiration of abscesses sometimes enables identification of the organism.

TREATMENT

As with other species of *Enterobacteriaceae*, effective antimicrobial therapy for *Citrobacter* is challenged by the continuing worldwide emergence of a broad array of β -lactamases, including metallo- β -lactamases (MBL).⁵³ Many different types of β -lactamases, including a novel TEM-type (TEM-134),⁸¹ the class A β -lactamase CKO,⁸² and a VIM-1 metallo- β -lactamase, have been described in various isolates of *Citrobacter*.¹¹⁸ Most *C. koseri* organisms are resistant to ampicillin (97% in one series)⁶⁴ and susceptible to aminoglycosides and third-generation cephalosporins.²³ A 4-year experience with neonatal septicemia caused by *C. koseri* has been described, however, in which all of 13 isolates were resistant to gentamicin but susceptible to third-generation cephalosporins.²⁷ The resistance patterns of *C. freundii* were reported in a national surveillance study of nosocomial bloodstream infections.⁸³ Of the 23 *C. freundii* isolates tested, resistance to piperacillin, piperacillin/tazobactam, ceftriaxone, and ceftazidime was a common (39% to 48%) finding. Isolates generally were susceptible to the aminoglycosides and ciprofloxacin (91% to 96%), and all *C. freundii* tested were susceptible to cefepime and imipenem.

The growing challenge of antimicrobial resistance amongst *Citrobacter* sp. is exemplified by a study performed in a tertiary care facility in India of bacterial isolates identified from 2010 to 2013.⁸⁶ Of 221 *Citrobacter* isolates, 179 (81%) were found to have diminished susceptibility to carbapenems. These resistant isolates were capable of elaborating extended-spectrum- β -lactamases as well as MBLtransferable on plasmids. Additional reports have confirmed the presence of *Klebsiella pneumoniae*

FIG. 101.1 Computed tomography scans showing progressive abscess formation and encephalomalacia in an infant (A) at 3 weeks of age and (B) 6 weeks of age, despite bacteriologic cure of *Citrobacter* meningitis.

carbapenemase-2 (KPC-2) from *Citrobacter* isolates.^{13,71} Some *Citrobacter* isolates contain chromosomally mediated group I β -lactamases. These bacteria possess a gene that, when triggered by exposure to cephalosporins or by spontaneous mutation, produces a cephalosporinase capable of inactivating cephalosporins.⁴⁷ Clinically, it manifests as treatment failure and emergence of drug resistance to various cephalosporins despite initial susceptibility.⁷⁰ In one study, the presence of group I β -lactamases was much more common with *C. freundii* (9 of 22 isolates) than with *C. koseri* (0 of 7 isolates).⁴⁷ Resistance was associated with previous receipt of an extended-spectrum β -lactam antibiotic. Reliable estimates of the percentage of *Citrobacter* strains that contain the chromosomal resistance gene are difficult to obtain because most studies lump *Citrobacter*, *Enterobacter*, and *Serratia* isolates together. In one Korean study, of 152 *Enterobacter/Citrobacter/Serratia* isolates, 45 (30%) were derepressed Amp C mutants.⁷⁹ In an in vitro study, Amp C production was inducible in eight of nine clinical isolates of *C. freundii* and in one of three isolates of *C. koseri*. Amp C synthesis was stably derepressed in 1/9 *C. freundii* isolates.²⁴ In contrast, an investigation from Johns Hopkins University Hospital of isolates collected in 2010 detected Amp C β -lactamases in only 1% of *Citrobacter* spp.^{1,109} Cefepime seems to be less likely to induce production of these β -lactamases and more resistant to hydrolysis by them,^{96,109} although a highly cefepime-resistant strain has been described.⁷ Of 3030 ceftazidime-resistant *Enterobacteriaceae* in a US study, 99% retained susceptibility to imipenem and 96.7% of ceftazidime-resistant *Citrobacter* isolates were susceptible to cefepime.⁸⁴ Quinolone resistance via *qnr* genes has also been found in *C. koseri*⁴⁹; in one study from Korea, 29% of *C. freundii* isolates were quinolone resistant. Most of these had *qnrB* genes.⁴⁸ Extensively resistant isolates are more likely to be susceptible to colistin⁶⁷ and polymyxin B¹²⁴ than to tigecycline; however there is a paucity of experience in the use of these antimicrobials for treatment of *Citrobacter* infections.

Treatment of *Citrobacter* meningitis often requires a multidisciplinary effort involving the neurosurgeon and the pediatrician. Although cerebral abscesses usually are aspirated or drained surgically, some patients are treated with antibiotics alone, and neither approach is clearly shown to be superior. When abscesses are inaccessible or small and not progressive, conservative management may be considered.²³ Ventriculostomy and craniectomy with open drainage of abscesses have been required in some children to effect bacteriologic cure, and placement of a shunt for hydrocephalus often is required.

Generally, antimicrobial therapy for gram-negative neonatal meningitis has proved disappointing (see Chapter 66).^{72,73} While no evidence supports one combination of antimicrobials over another in the treatment of *Citrobacter* meningitis, initial therapy usually combines a third- or fourth-generation cephalosporin or carbapenem (usually meropenem) with an aminoglycoside.²³ Careful evaluation of pharmacodynamic and

pharmacologic data has led to a recent recommendation to consider meropenem as the preferred antimicrobial for therapy of *C. koseri* infections.²² Chloramphenicol,^{21,33,41} imipenem-cilastatin,^{25,41} and trimethoprim-sulfamethoxazole³⁶ also have been used successfully.

Poor meningeal penetration of aminoglycosides in addition to the presence of intracranial abscesses render antibiotic therapy for *Citrobacter* meningitis especially difficult. The ability of this organism to persist in the brain is shown by its recovery 4 years after neonatal infection.²⁵ Cranial computed tomography usually is used for evaluation of complications such as hydrocephalus and multicystic encephalomalacia (Fig. 101.1). Administration of antibiotics intrathecally or directly into abscess cavities has been tried but has not been shown convincingly to be beneficial.^{36,37,40,55,63,76,93,108,116}

In a randomized controlled trial, intraventricular administration of gentamicin in the treatment of neonates with gram-negative meningitis was associated with a poorer outcome.⁷⁴

Neonates with gram-negative meningitis should undergo repeat lumbar puncture approximately 72 hours after beginning therapy to document sterilization of cerebrospinal fluid. Duration of therapy with intravenous antibiotics generally is a minimum of 21 days for gram-negative neonatal meningitis. For cases complicated by intracranial abscesses, prolonged therapy (usually 4 to 6 weeks after sterilization of cerebrospinal fluid) is indicated.^{23,54}

Scrupulous attention to preventive infection control practices has been recommended to stem nursery outbreaks.^{33,80,122} These prophylactic measures include care of skin and the umbilical cord, elimination of crowding with isolation of infected infants and carriers, and good hand washing practices. Exclusion of colonized personnel and temporary closing of the nursery have been followed by a reduction in neonatal *C. koseri* colonization. Although cohorting of colonized infants is a reasonable practice, multiple sources of introduction of *Citrobacter* may limit the efficacy of this approach in some outbreaks.³¹

Treatment of *Citrobacter* infection beyond the neonatal period requires choice of an appropriate antimicrobial, with drainage of abscesses and débridement of wounds. Therapy should be guided by antimicrobial susceptibility testing. Outcome depends largely on the preceding debility of the host and location of the infection. Significant mortality is associated with immunocompromised patients with septicemia or pulmonary disease.^{46,50,64,69,101}

Acknowledgments

We thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Enterobacter

Laura A. Sass • Randall G. Fisher

Enterobacter is a genus of Enterobacteriaceae that is an increasingly frequent cause of health care–associated pediatric infection. *Enterobacter* can cause infection of postsurgical wounds, meningitis, and infection of the gastrointestinal, urinary, and respiratory tracts. Development of resistance to antibiotics commonly used for treatment of infection is an increasingly common challenge. For a more detailed overview of *Enterobacter* spp., the reader is referred to the review by Sanders and Sanders.¹⁸⁷

BACTERIOLOGY

Enterobacter spp. are named for their enteric recovery as gram-negative bacteria.¹⁸¹ They commonly are found in soil, water, and sewage. More reports are appearing of resistant species found in the community, often in hospital wastewater.^{213,227} *Enterobacter* spp. also cause botanical disease. These organisms are facultatively anaerobic and motile by peritrichous flagella, with the exception of *E. asburiae*. Most species yield positive results on malonate, citrate, sucrose fermentation, and Voges-Proskauer tests. *Cronobacter sakazakii* (formerly known as *E. sakazakii*) is distinguishable from the other species by its yellow-pigmented colonies.⁹⁴ There are now at least seven species included in the *Cronobacter* genus, with *C. sakazakii* remaining the predominant human pathogen.^{59,215} Taxonomic studies have led to several classifications of species contained in this genus. With the reclassification of *E. agglomerans* as *Pantoea agglomerans* (see Chapter 114), *E. cloacae*, *E. hormaechei*, and *E. aerogenes* are the most common species recovered from clinical material.^{8,18,34,37,53,66,96,139,221,223}

Additional species in the *Enterobacter* genus rarely recovered from human infections include, *E. asburiae*, *E. cancerogenus* (formerly *E. taylorae*), *E. kobei*,¹¹¹ *E. cloacae* subsp. *dissolvens*, *E. massiliensis*,¹¹⁶ *E. bugandensis*,⁴⁹ and *E. hormaechei*.^{1,39,70,88,105,137,138,151,181,226} *E. ludwigii* is another new species isolated from clinical specimens that is closely related to the *E. cloacae* complex.⁸⁹ Numerous former *Enterobacter* species have been reclassified into new genera including *E. cowanii* as *Kosakonia cowanii*, *E. intermedius* as *Kluyvera intermedia* (formerly *Kluyvera cochleae*),¹⁶² *E. amnigenus* and *E. nimipressuralis* as *Lelliottia amnigenus* and *L. nimipressuralis*, as well as *E. gergoviae* as *Pluralibacter gergoviae*.^{24,154}

EPIDEMIOLOGY

Enterobacter is encountered most commonly as a hospital-acquired pathogen in patients with chronic illness.^{8,18,37,53,96,221,223,231} A surveillance study at 50 American medical centers showed *Enterobacter* as the eighth most common cause of health care–associated bloodstream infections, accounting for 230 of 4725 (5%) isolates.¹⁶⁹ Of these, 71% were *E. cloacae*, 23% were *E. aerogenes*, and 6% were other species of *Enterobacter*. *Enterobacter* infections are particularly common in intensive care units (ICUs).¹⁴¹ A report from the Centers for Disease Control and Prevention (CDC) describing the epidemiology of health care–associated infections in 61 pediatric ICUs in the United States revealed that *Enterobacter* spp. were isolated with increasing frequency from patients with pneumonia and were the most common gram-negative isolates from bloodstream infections.⁹⁶ The frequency of *Enterobacter* spp. increased from 7% to

hospital-acquired pathogen

12% of reported pathogens over a 6-year period. *Enterobacter* spp. also accounted for 6% of health care–associated blood stream infections in a prospective collection of surveillance data from an Australian public hospital system¹⁹⁴ and were found to cause 22% of the neonatal gram-negative infections from neonatal ICUs (NICUs) in the UK.¹⁰⁴ *Enterobacter* spp. also were found to be second only to *Pseudomonas aeruginosa* in prevalence in health care–associated sinusitis.¹⁸²

In other CDC surveys focusing on data from the National Healthcare Safety Network (NHSN), *Enterobacter* was one of the five pathogens most commonly encountered in ICUs and accounted for 5.0% to 8.6% of reported health care–associated infections.^{85,96} In one large academic hospital, the relative proportion of *Enterobacter* spp. in health care–associated infections had decreased as a result of an increase in gram-positive and anaerobic infections.¹⁰¹ During a 10-year period in six Brazilian NICUs, gram-negative pathogens accounted for more than half of all bloodstream infections, with *Enterobacter* spp. representing 2%.⁴¹ In Canada, similar results were found in a nationwide surveillance program, with *E. cloacae* found in 2.2% of all health care–associated infections, including blood, wound, and urine sources.²³⁸ Multiple outbreaks caused by *Enterobacter* have been described in neonatal ICUs.^{71,86,186} *E. cloacae* has been found in some NICUs as the predominant pathogen, representing almost 40% of bloodstream isolates,¹³⁰ in addition to being responsible for outbreaks of sepsis.⁴⁴ In some series, one-third of *Enterobacter* bacteremias were polymicrobial, which represents a greater prevalence than that of bacteremia caused by other gram-negative organisms.^{21,66}

The most frequently cited risk factor for *Enterobacter* infection is the recent receipt of antibiotics, particularly third-generation cephalosporins.^{4,7,8,17,26,66,97,218} Other risk factors include prolonged hospital stay (especially in an ICU), presence of serious underlying illness (e.g., burns, malignancy, and diabetes); prematurity in a neonate; immunosuppression; organ transplantation; and the presence of a foreign device.* Vertical spread of *Enterobacter* from mother to infant may occur at the time of birth,⁶⁴ but infant colonization is usually from an environmental source. A surveillance program in an NICU that screens for *E. cloacae* colonization determined that only 8.8% of colonized infants were the result of mother-to-child transmission.⁷¹ Environmental sources implicated in outbreaks of infection have included intravenous fluids,^{9,28,31,131,134,204,216,220,222} chronic hand dermatitis of a care provider,¹² contaminated infant formula,^{10,15,30,38,150} blood gas machines,^{2,115} contaminated transesophageal echocardiography probes,⁹⁹ cardioplegia ice,²⁵ therapeutic bed mattresses and mattress covers,²⁰⁹ and rectal thermometers.²⁰⁸

Ribotyping, pulsed-field electrophoresis, and restriction-fragment polymorphism analysis of DNA from clinical isolates have been useful in discriminating possible sources of contamination and patient-to-patient transfer of individual strains.[†] Integrins, discrete mobile units of DNA that can confer antibiotic resistance, have been reported in *Enterobacter* spp. and are more common findings in infections acquired in a health care setting.⁴³ Molecular diagnostic testing has proved useful in outbreak situations, especially in tracking antibiotic-resistant strains caused by plasmid acquisition of extended-spectrum β -lactamases (ESBL).⁶⁹ Most cases are not outbreak-associated, and endogenous origin of infection is a more common means of acquisition than is the patient's environment.¹⁶⁹ This factor explains why recent antimicrobial use by the patient is such a strong predictor of infection.

PATHOPHYSIOLOGY

Newborns often are colonized by *Enterobacter* spp. in the gastrointestinal tract soon after birth,^{14,160} and acquisition of hospital strains, including ESBL-producing strains, in immunocompromised newborns is common.^{7,14,58,65,92,211} *Enterobacter* spp. may contaminate the compromised respiratory tract. The oropharynx commonly is colonized by *Enterobacter* by the time the infant is 1 month of age; colonization rates generally are lower in breast-fed infants.¹¹ Newborns with gastrointestinal abnormalities requiring prolonged parenteral nutrition have higher rates of colonization with *Enterobacter* and a higher incidence of

sepsis.^{170,171} Other risk factors for increased *Enterobacter* colonization in neonates include prematurity and prior antibiotic use.¹⁶⁴ Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults, but increased colonization, including increased risk for third-generation cephalosporin-resistant strains, especially with prior cephalosporin treatment of at least 3 days, is noted during illness.²²⁵

The ability of *Enterobacter* spp. to develop inducible resistance to penicillins and cephalosporins increases their pathogenic potential. All *Enterobacter* spp. possess an inducible chromosomally encoded class C (Bush group I) β -lactamase type cephalosporinase (*ampC*), which usually is produced in small amounts, conferring resistance to both first- and third-generation cephalosporins.¹⁸⁷ An inducible plasmid-encoded *ampC* (gene *bla*_{ACT-1}) also has been described and can be present in *Enterobacter* spp. and other Enterobacteriaceae.¹⁸⁴ Both enzymes have a high affinity for third-generation cephalosporins but a low maximum hydrolysis rate.¹³⁷ Consequently β -lactamase mediates resistance to these antibiotics only when it is produced in large quantities or large numbers of plasmids are present.^{123,180}

Resistance emerges after a mutation occurs in the *ampD* gene, which normally prevents high-level expression of β -lactamase.^{95,98} Such mutants are considered “stably derepressed” and may be induced by exposure to β -lactam antibiotics, especially ampicillin and cephalosporins. Mutations in the *ampR* gene produce similar effects.¹¹⁴ The addition of a β -lactamase inhibitor (e.g., clavulanic acid) does not increase the activity of β -lactam antibiotics against *Enterobacter* spp.; rather, it may decrease the activity against the organism by inducing the class C β -lactamase, as can the presence of *ampR* mutants.^{98,114,212}

Emergence of resistance can occur during therapy for an isolate that initially is shown to be susceptible.^{84,187} Resistance can be detected 24 hours after initiation of therapy or may be delayed 2 to 3 weeks.³⁶ Reports of resistant strains of *Enterobacter* that produce plasmid-mediated, ESBL began to be published in 1993 and have persisted over time.^{90,132,172} Various ESBL genes, including genes from the TEM, SHV, and CTX-M families, have been found.^{29,69,159,198,237} This variation can complicate choosing antimicrobial agents because discerning the source of the β -lactam resistance in the clinical microbiology laboratory often is difficult without performing specific testing, such as the double-disk diffusion method. Newer rapid methods of identification, such as rapid biochemical tests for ESBL and carbapenemase producers, polymerase chain reaction (PCR) technology, and mass spectroscopy are becoming more prevalent in the clinical microbiology laboratory, replacing the traditional double-disk diffusion methodology.⁵⁶ A survey of 11 clinical laboratories in Germany to determine ESBL prevalence found that 40% of *E. cloacae* complex organisms were resistant to extended-spectrum cephalosporins, and only 6% carried ESBL genes.⁹⁰ This finding is in contrast to other reports with prevalences of 36% in some Asia-Pacific regions.¹³ There continues to be wide variability in the prevalence of multidrug resistance throughout the world.

The global spread of carbapenemase-producing Enterobacteriaceae (CRE) has affected *Enterobacter* spp. as well as other members of the class. Infections with these multidrug-resistant organisms have been reported worldwide. Class A carbapenemases are plasmid-mediated, effectively hydrolyze carbapenems, and are partially inhibited by clavulanic acid, with one of the most common being *Klebsiella pneumoniae* carbapenemases (KPC).¹⁴⁹ KPC-mediated resistance in *Enterobacter* spp. has been reported.^{125,190} Class B metallo- β -lactamases (MBLs) are Verona integron–encoded metallo- β -lactamase (VIM), New Delhi metallo- β -lactamase–1 (NDM-1), and IMP (imipenem resistance gene). VIM producers can be endemic to a certain region, but have been reported globally in outbreaks and sporadic infections.^{79,83,155} These enzymes hydrolyze all β -lactam antibiotics, including carbapenems, but do not hydrolyze monobactams such as aztreonam. NDM-1 producers have also been reported worldwide and are likely endemic in India. These genes are not associated with a single clone and have varied resistance to carbapenems. Of concern is the likelihood of other antibiotic resistance genes to be included on the *bla*_{NDM-1} gene, including ESBL, aminoglycoside, macrolide, and rifampin resistance.^{27,149} The CDC had three reports of NDM-1 isolates in 2010, one of which was *E. cloacae*. All patients had recent medical care in India as their risk factor.³³ Class D OXA- β -lactamases have also been reported in *Enterobacter* species. They

*References 3, 43, 62, 86, 93, 128, 186, 187, 200, 214, 239.

†References 16, 25, 30, 37, 38, 76, 81, 82, 118, 168, 187, 191, 210.

are serine-carbapenemases along with oxacillinases and are generally plasmid-mediated, conferring broad-spectrum resistance to cephalosporins due to point mutations in the enzyme itself.^{57,61} The prevalence of CRE is increasing in the United States, especially in the adult population. A seven-region survey of the United States for CRE found an incidence of 2.93 per 100,000 population, with regional differences. Most of the cases were isolated from urine and were associated with prior hospitalizations, indwelling devices, or residence in long-term chronic care facilities.⁷⁸ The Surveillance Network-USA database reviewed antimicrobial susceptibilities of Enterobacteriaceae from 1999 to 2012, finding that 0.08% were CRE. The CRE infection rate increases were highest for *Enterobacter* spp., blood culture isolates, and isolates originating from an ICU setting. This is still a low overall rate, but it did increase 3% to 5% over the course of 12 years.¹²⁶

In one study, gram-negative fecal aerobic flora were eradicated completely after 24 hours of ceftriaxone therapy, only to be replaced within 10 days (mean, 6.7 days) of therapy by *P. aeruginosa*, *Enterobacter*, and *Citrobacter* resistant to all β -lactam antibiotics.⁷⁷ Although uncommon, the combination of reduced outer-membrane permeability and high-level β -lactamase production renders some clinical isolates of *E. resistant* to carbapenems (imipenem, meropenem, and ertapenem) and fourth-generation cephalosporins (cefepime).^{19,47,50,120,122,137,166,199,206}

Other than the presence of endotoxin, factors responsible for the virulence of *Enterobacter* spp. are not well defined but may include cytotoxins, type III secretion systems, altered pili, and efflux pumps.^{103,113,119,156,158,167} In vitro, it is possible to transfer and express an *Escherichia coli* enterotoxigenic plasmid in *Enterobacter*, implying the potential for transfer of virulence factors to *Enterobacter* spp. from other species.²³⁶ Shiga toxin-producing *E. cloacae* has been isolated from the stool of a 5-month-old girl with hemolytic-uremic syndrome.¹⁶¹ Shiga-toxin producing *E. coli* OR:H9 also was isolated from the child's stool, rendering the cause of the child's symptoms unclear. Similar to other organisms associated with central venous catheter infections, *Enterobacter* spp. may adhere irreversibly to catheter material, promoting colonization and infection via biofilm formation.^{108,106,165} Certain ribotypes have been encountered more commonly as community or blood stream isolates, indicating the presence of as yet undefined factors affecting virulence.²²⁴ The propensity of *C. sakazakii* to produce neonatal meningitis complicated by abscesses and cerebral infarction is unexplained.^{15,38,158,230} Proposed mechanisms have included brain capillary and intestinal endothelial cell invasion, persistence in human macrophages, biofilm formation, and a possible role for outer membrane protein A (OmpA).^{42,108,143,144,202,203}

CLINICAL MANIFESTATIONS

Infection caused by *Enterobacter* commonly is indistinguishable from illness caused by other enteric pathogens. Sources of infection include central venous catheters and the urinary and biliary tracts.^{8,10,66,87,96,127} *Enterobacter* commonly colonizes the respiratory tract secretions of intubated patients, and it is implicated increasingly as a cause of ventilator-associated pneumonia.^{96,182,189} It can also be a cause of severe community-acquired pneumonia, generally in patients with serious comorbidities. This type of pneumonia strongly resembles health care-associated pneumonia, and patients may appear septic. Empirical antibiotic therapy may be very difficult because of unpredictable resistance patterns.²³ It also is one of the most common causes of pneumonia after lung transplantation¹²⁹ and can be found as part of the oral flora in patients with strokes.⁷⁵ Neonatal infection warrants special mention because of the prominence of *Cronobacter sakazakii* as a cause of devastating meningitis.

Similar to *Citrobacter koseri* (see Chapter 101), *C. sakazakii* causes neonatal meningitis complicated by cerebral abscesses or infarctions.^{15,32,38,51,102,230,232} Poor feeding, irritability, jaundice, a full anterior fontanelle, and fever or hypothermia are presenting features shared with other gram-negative causes of bacterial meningitis. The mortality rate has been reported to range from 33% to 80%, and almost all survivors experience severe neurologic complications, including quadriplegia, developmental impedance, and impaired sight and hearing.^{51,230} This severe morbidity is consistent with the development of multiple cystic

lesions of the brain in 50% of surviving neonates. Serial computed tomography (CT) scans commonly reveal evolution of lesions most consistent with initial cerebral infarction, rather than primary abscess formation.^{67,117,230} Subsequent cystic lesions may be purulent abscesses, from which the organism can be cultured; alternatively, they sometimes represent sterile fluid collections.²⁷ Meningitis tended to develop in infants of greater gestational age and birth weight than in infants with only bacteremia, but they tended to be younger in chronologic age.²²

Enterobacter also may be associated with necrotizing enterocolitis in the newborn, which became more apparent during the outbreaks of *C. sakazakii* associated with contaminated powdered infant formula.^{117,207} *Enterobacter* spp. were the third most common isolate recovered from peritoneal fluid in a series of patients with necrotizing enterocolitis.^{117,146}

In older immunocompromised children, bacteremia complicated by sepsis is a significant risk. Central venous catheterization and gastrointestinal tract pathologic processes seem to pose greater risks for development of bacteremia than infection of the urinary tract. Bacteremia is accompanied by shock in almost one-third of patients, but disseminated intravascular coagulation occurs in fewer than 5%.^{17,21,66} Seeding of metastatic foci is uncommon. Overall case-fatality rates with bacteremia vary but usually are approximately 30%.¹⁸⁷ Predictors of poor prognosis include age younger than 18 months, inadequacy of antimicrobial chemotherapy, infection with extended-spectrum cephalosporin-resistant isolates, septic shock, type of underlying disease, presence of pulmonary infection, thrombocytopenia, unknown primary site of infection, and requirement for intensive care.^{17,21,34,46,66,100,133} Absence of fever during the course of infection may be a particularly ominous sign; four of five afebrile subjects died in one series.¹⁷ One study found that the use of an aminoglycoside as part of the empirical antibiotic management was a factor contributing to survival of *Enterobacter* or *Citrobacter* bacteremia.⁴⁶

Some *Enterobacter* spp. recovered from children with diarrhea have been reported to produce enterotoxin,³⁵ although a causative role in enteritis has not been established. Other presentations of *Enterobacter* infection include endophthalmitis,^{110,140,142} endometritis,⁷³ wound infections,⁶⁶ diskitis,^{175,196} endocarditis,²⁰⁵ and osteomyelitis.^{40,52,109,197} *Enterobacter* also has caused syndromes classically associated with other agents, such as gas gangrene,⁶⁰ childhood purpura fulminans,⁸⁰ ecthyma gangrenosum,¹⁷⁶ and necrotizing fasciitis.¹¹²

DIAGNOSIS

Diagnosis of infection caused by *Enterobacter* relies primarily on isolation of the organism in culture from clinical material. Motility, production of ornithine decarboxylase, and the absence of deoxyribonuclease help distinguish the genus from *Klebsiella* and *Serratia*. The presence of yellow-pigmented colonies can help identify *C. sakazakii*. Patterns of sugar fermentation and production of decarboxylase also distinguish the species. Molecular techniques that are becoming available for rapid identification of bacteria include PCR single-strand conformation polymorphism analysis using 16S ribosomal DNA. This technique allows the potential identification of pathogens to be made from a wide range of clinical specimens with low numbers of bacteria.^{228,234} Matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF) and real-time PCR for rapid nonculture detection of *Enterobacter* and other clinical isolates are becoming more common in the clinical setting.^{135,163,183} In light of the increase of *C. sakazakii* invasive disease after ingestion of contaminated powdered infant formula, several techniques have been introduced for the rapid identification of this pathogen clinically and in foodstuffs. The use of a specific PCR amplification of the outer membrane protein A gene (*ompA*) is being investigated,¹⁴⁵ as is reverse-transcriptase¹²⁴ and the use of selective media.^{5,48,107} DNA microarray technology is also being investigated for use.²¹⁹ Ribotyping is a highly discriminatory and reproducible method for the typing of *E. cloacae*, the most common cause of infection.⁶⁸ Other useful molecular techniques include restriction endonuclease analysis of chromosomal DNA, pulsed-field gel electrophoresis, random amplification of polymorphic DNA, and amplification of short interspersed repetitive sequences.¹⁸⁷ Most often, molecular typing

methods are used in concert with biotyping, serotyping, or bacteriocin typing.

TREATMENT

Treatment of *Enterobacter* infection is made problematic by inducible resistance to cephalosporins and intrinsic resistance to aminopenicillins, cefazolin, and cefoxitin.²⁰ The recognition that *Enterobacter* spp. may carry ESBL plasmids in addition to expressing chromosomal *ampC* β -lactamases can be problematic using automated ESBL detection systems. The use of the double-disk synergy method for ESBL detection can indicate the presence of plasmid-mediated resistance but is challenging because high production of *ampC* can mask the inhibition of ESBL by clavulanic acid.²²⁹ New selective media for the identification of ESBL-producing isolates are available but still may have problems with high *ampC* producers.^{177,179} Identification of carbapenemase-producing isolates is more difficult, although there are increased commercial applications becoming available such as rapid biochemical tests for both ESBL and carbapenemase producers.^{56,173,174} The Clinical and Laboratory Standards Institute (CLSI) lowered carbapenem breakpoints in the United States in 2010 to allow for better identification, and these were also lowered in Europe in 2013 by the European Committee on Antimicrobial Susceptibility Testing (EUCAST). They are not perfect, and the use of molecular confirmation for ESBL carriage is suggested.¹⁴⁷ The modified Hodge test has potential, but, like the double-disk synergy method for ESBL detection, it is manual and can be time-consuming while still lacking in specificity and sensitivity (e.g., allows detection of high-level *ampC* producers, but has weak detection of NDM-1 producers). Molecular techniques, mostly PCR, are now the standard for detection.¹⁴⁹ It is important to know the local antibiotic resistance patterns to determine the risk for multidrug resistance. Therapeutic options in this setting can include the use of older medications, including fosfomycin and colistin, in addition to newer antibiotics such as tigecycline and doripenem.⁷²

Antibiotic resistance may be present at the time of initial isolation or may develop during therapy.^{37,84} This problem is compounded by the common observation of resistance to extended-spectrum penicillins and, to a lesser extent, aminoglycosides.⁶ The risks for development of resistance to cephalosporins, piperacillin, and aminoglycosides have been reported to be higher at a tertiary care center than at a primary care hospital.⁵⁵ Previous administration of third-generation cephalosporins increases the risk for having multiresistant *Enterobacter* isolates in an initial positive blood culture.^{8,36,148} Hospitalized newborns quickly may acquire multiresistant strains, even though they themselves have not been treated with cephalosporins.¹⁴ Isolation of multiresistant *Enterobacter* spp. in blood culture is associated with a higher case-fatality rate in contrast to mortality after isolation of a more sensitive strain.^{36,192} A recent study from the United Kingdom noted that increased mortality from gram-negative infections, including *Enterobacter* spp., was associated with increasing gentamicin minimum inhibitory concentration (MIC), even for isolates deemed susceptible.¹⁰⁴ Although less common, resistance to imipenem has been reported.^{54,120,201} Cefepime, a fourth-generation cephalosporin, generally maintains activity against *Enterobacter* spp. that possess the class C β -lactamase,¹⁸⁸ although MICs may be higher.¹³⁷

Emergence of cefepime resistance during therapy has been described in a liver transplant recipient with a hepatic abscess caused by *E. aerogenes*.¹²² The accompanying editorial warns about the risk for failure using cefepime in patients who have high-density infections (e.g., poorly drained liver abscess) caused by ceftazidime-resistant strains of *Enterobacter*.¹³⁷ The presence of an SHV-type ESBL has been associated with cefepime resistance, highlighting the need to identify those strains.¹⁹⁶ Vigilant antibiotic stewardship may aid in decreasing resistance. One institution restricted the use of cefepime and compared the 2 years before with the 2 years after the policy, demonstrating an improvement in ciprofloxacin susceptibility in their *Enterobacter* clinical isolates.¹⁵²

In a nationwide survey of nosocomial bloodstream infections, rates of *Enterobacter* resistance to third-generation cephalosporins (ceftazidime, ceftriaxone) and broad-spectrum semisynthetic penicillins (piperacillin) with or without a β -lactamase inhibitor (tazobactam) was high, ranging

from 35% to 50%.¹⁶⁹ Cefepime and imipenem inhibited 97% to 100% of isolates. Susceptibility to aminoglycosides and fluoroquinolones ranged from 92% to 98%, and 85% to 96% of isolates were susceptible to trimethoprim-sulfamethoxazole. Fluoroquinolone resistance is now being reported and likely is plasmid-mediated.^{157,235} Plasmid-mediated quinolone resistance can be more common in ESBL-producing isolates as well, so caution should be used.¹⁹⁵ Because resistance patterns may vary based on geographic location, local susceptibility data should be used to guide initial therapy.

Some investigators recommend initial combination therapy that includes an aminoglycoside plus either cefepime or a carbapenem (imipenem or meropenem), until results of susceptibility testing are available. Third-generation cephalosporins should be used with caution, even when initial susceptibility results seem favorable. When strains are resistant to gentamicin and tobramycin, amikacin may be a suitable alternative. Good responses to therapy and return of gentamicin susceptibility of hospital *Enterobacter* strains have occurred after routine substitution of amikacin for gentamicin.^{178,193} Trimethoprim-sulfamethoxazole alone (or combined with an aminoglycoside) and quinolones seem to be good alternatives for the treatment of *Enterobacter* infections, including meningitis.^{8,45,74,138,232} Fluoroquinolones have been reported to be effective in bone and joint infections, in combination with cefepime.¹²¹ Tigecycline has been used for the treatment of multidrug-resistant strains, although reports of resistance are emerging.^{91,217,233} Colistin has also been used, but it is hampered by its side-effect profile. As newer antimicrobial agents become available, more testing will be required to determine their effectiveness. Ceftazidime-avibactam, a combination drug with a novel non- β -lactam/ β -lactamase inhibitor that inhibits class A, class C, and some class D enzymes, may have some promise in treating these difficult infections.¹⁸⁵

Enterobacter meningitis creates special concerns. As is common with other forms of neonatal enteric meningitis, even susceptible organisms often persist in cerebrospinal fluid for 5 days or longer.¹⁰² Monotherapy with a cell wall-active agent seems to be less effective than combination therapy with an aminoglycoside. Trimethoprim-sulfamethoxazole also has been used successfully.^{63,232} Intrathecal administration of antibiotics does not seem to be beneficial in infants,¹³⁶ but it has been used with some success in adults.¹⁵³ The physician should anticipate the potential development of cerebral abscesses, infarctions, and cysts in newborns with *C. sakazakii* infection. Serial CT scans should be considered, and a neurosurgeon should be sought for drainage of abscesses and management of fluid accumulation.

103

Extraintestinal Pathogenic *Escherichia coli*

Patrick C. Seed

Escherichia coli are ubiquitous among terrestrial mammals, including humans, occupying approximately 0.1% of the microbes in the human enteric tract.²⁵ *E. coli* is a common commensal with normal homeostatic functions within intestinal-associated microbial communities. However, some subtypes are virulent and produce infectious diseases.^{57,66} Genetic mutations and the loss and gain of genetic material through genetic rearrangements, transposons, phages, and plasmids have produced *E. coli* lineages with a wide capacity to occupy different host niches and yield different clinical syndromes.⁶⁶ Animal and human subtypes are closely related and in many cases are the same, differentiated based only on the hosts from which they were isolated. The pathotypes of *E. coli* have specific associated virulence factors and genetic islands.

E. coli is the common cause of a wide range of bacterial infections within and outside of the intestinal tract, including traveler's diarrhea, dysentery, cholecystitis, cholangitis, urinary tract infection (UTI), bacteremia, neonatal meningitis, and pneumonia (Table 103.1). The pathogenic *E. coli* may be divided into two major categories: extraintestinal pathogenic *E. coli* (ExPEC) and diarrheagenic *E. coli*. ExPEC is the focus of this chapter.

E. coli are facultative anaerobic gram-negative bacilli in the Enterobacteriaceae family.⁴⁰ Common physiologic and biochemical features include fermentation of lactose (~90% of isolates), indole production, and lysine decarboxylase activity.⁷³ Many isolates are motile, with peritrichous flagella constituting one of 56 flagellar antigen (H) serotypes.⁷¹ In addition, there are 171 somatic antigens (O). The most common O subtypes have been reported as O1, O2, O4, O6, O7, O8, O18, O25, O68, and O75.^{13,35,103,128}

EPIDEMIOLOGY

E. coli produces three major types of extraintestinal invasive diseases in children: (1) UTIs, (2) bacteremia and sepsis, and (3) meningitis. Lower incidence infections produced by ExPEC include pneumonia, osteomyelitis, and endocarditis. Antibiotic resistance in ExPEC has undergone a shift in the past decade and has important implications in the treatment of ExPEC-related infections. In particular, ExPEC sequence type 131 (ST131), a pandemic community-associated strain, is frequently multidrug resistant (three or more antibiotic classes).¹⁰⁴

Urinary Tract Infection

E. coli is the leading cause of culture-proven UTI in children, producing more than 80% of community-acquired UTI, regardless of the presence

of vesicoureteral reflux.⁴⁵ Other etiologies in pediatric community-acquired UTI include *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterococcus* spp., and, primarily in female adolescents, *Staphylococcus saprophyticus*. *E. coli* is also the leading cause of hospital-acquired UTI among children. Unlike in adult patients, in whom *E. coli* may account for more than 50% of nosocomial UTIs, *E. coli* produces approximately 30% of nosocomial UTIs in children.^{69,75} Organisms such as *Candida* spp., *Klebsiella* spp., and *Pseudomonas aeruginosa* collectively assume a greater proportion of pediatric nosocomial UTIs.

In general, the prevalence of UTI is 7% among infants with febrile illness, of which, as noted earlier, *E. coli* is by far the most likely cause.¹¹³ Among female infants, 7.5% with febrile illnesses have a UTI. Of male infants, the prevalence differs greatly based on whether the infant is circumcised. Among uncircumcised male infants, the prevalence of UTI is 20.1%, in contrast to a prevalence of 2.4% among those who are circumcised. Circumcision status does not alter the high proportion of UTIs associated with *E. coli*. Black infants have a lower prevalence of UTI, at approximately 4.7%, in contrast to white children, at 8%. The prevalence of UTI drops significantly after age 1 year, but increases during adolescence such that the pooled prevalence among children younger than 19 years of age is 7.8%.¹¹³ Factors increasing the risk for UTI include vesicoureteral reflux, bladder dyssynergia, other urinary tract anomalies, sexual intercourse, spermicide use, pregnancy, and diabetes mellitus (Table 103.2).

Fever without localizing signs is a major cause of presentation for medical care among infants younger than 90 days of age. Recent studies indicate that in the era of vaccinations for *Haemophilus influenza* type b and *Streptococcus pneumoniae*, *E. coli* UTI is the leading cause of fever without localizing signs.^{129,130} UTI was responsible for 76% of all episodes, and bacteremia and meningitis were 19% and 3%, respectively. Of the UTIs, *E. coli* was the causative agent in 96% of the cases.

Some female children experience colonization of the bladder without urinary symptoms, termed asymptomatic bacteriuria (ASB). *E. coli* is also the most common cause of ASB. In U.S. female school children at 5 to 6 years of age, the incidence of ASB was observed to be 1.9% to 2.2%, whereas only 0.2% of age-matched boys had ASB.^{20,110} The cumulative prevalence of ASB between the ages of 6 and 12 years is reported to be 4.6%. No ethnic or socioeconomic risk factors have been associated with ASB. In addition to sex, risk factors include diabetes and sickle-cell disease.^{17,102}

TABLE 103.1 Major *Escherichia coli* Classifications

Main Group	Subgroup	Associated Diseases
Intestinal pathogenic <i>E. coli</i> (IPEC)	Enterohemorrhagic <i>E. coli</i> (EHEC)	Afebrile, bloody colitis
	Enteropathogenic <i>E. coli</i> (EPEC)	Watery diarrhea
	Enterotoxigenic <i>E. coli</i> (ETEC)	Watery diarrhea
	Enteraggregative <i>E. coli</i> (EAEC)	Chronic, persistent diarrhea
	Enteroinvasive <i>E. coli</i> (EIEC)	Watery diarrhea or dysentery
Extraintestinal pathogenic <i>E. coli</i> (ExPEC)	Uropathogenic <i>E. coli</i> (UPEC)	Urinary tract infection, urosepsis
	Neonatal meningitis <i>E. coli</i> (NMEC)	Meningitis
	Sepsis-causing <i>E. coli</i> (SEPEC)	Bacteremia, sepsis
Animal-associated pathogenic <i>E. coli</i> (AAPEC) reservoir groups	Avian pathogenic <i>E. coli</i> (APEC)	Bird sepsis, chronic respiratory disease, swollen head syndrome
	Mammary pathogenic <i>E. coli</i> (MPEC)	Bovine mastitis
	Endometrial pathogenic <i>E. coli</i> (EnPEC)	Bovine endometritis

TABLE 103.2 Risk Factors for Extraintestinal Pathogenic *Escherichia coli* Urinary Tract Infection in Children

Factor	Type	Mechanism	References
Female gender	Physical-anatomic	Shorter urethra and closer proximity to the rectum increases access of uropathogens to the urinary tract	135
Vesicoureteral reflux	Physical-anatomic	Reflux of urine through the ureteral valves moves contaminated urine from the bladder to the kidneys	7, 11, 114
Bladder dyssynergia	Physical-anatomic	Incoordination of voiding; failure to clear microbes	117
Urinary tract anomalies	Physical-anatomic	Urinary stasis; failure to clear microbes	7
Catheterization	Physical-anatomic	Introduction of organisms into urinary tract; persistence of less virulent organisms	70, 109, 123
Sexual intercourse	Behavioral	Introduction of periurethral organisms into urinary tract	26, 87
Spermicide use	Behavioral	Inhibition of vaginal lactobacilli with outgrowth of <i>E. coli</i>	46
Diaphragm use	Behavioral	Spring-rim-mediated minor bladder trauma; co-use of spermicidal gels	46
Diabetes mellitus	Immune	Glucosuria; neutrophil functional impairment	32, 89, 94

Bacteremia and Sepsis

E. coli may produce bacteremia or sepsis. Pediatric *E. coli* bacteremia and sepsis occur mostly in young infants and special groups of children such as patients with chemotherapy-induced immunodeficiency, central venous catheters, urinary tract anomalies, and human immunodeficiency virus.^{16,105} Patients in the neonatal and pediatric intensive care units have a heightened risk for bloodstream *E. coli* infections, as do patients with obstructive urinary tract disease and UTI, leading to urosepsis.

Among infants, *E. coli* bloodstream infections are most common in the first month of life, with decreasing numbers of cases in the second to third months of life. Among neonates, *E. coli* has been associated with approximately 18% of early-onset sepsis and a similar percentage of late-onset sepsis, placing it as the second or third most common etiology in this age group.¹²⁶ In preterm infants, the infection rate for *E. coli* was more than 10%, with a contemporary study demonstrating a rate of 29%.^{9,120} Prematurity, low birth weight, prolonged labor, prolonged rupture of membranes, intrapartum maternal fever, and maternal antibiotics may increase the risk for complicated, high morbidity or mortality infections.¹²⁴ Neonatal early-onset group B streptococcal disease has decreased significantly with the use of intrapartum ampicillin for women at risk because of known colonization, prolonged rupture of membranes, or maternal fever. However, more than 50% of *E. coli* organisms are resistant to ampicillin such that prophylaxis has not had a positive impact on early-onset *E. coli* infection. Retrospective data suggest that ampicillin-resistant *E. coli* may be responsible for more fulminant and higher mortality disease among premature infants,^{19,53} although this remains controversial and in need of further study.¹¹²

Meningitis

In the pediatric population, *E. coli* meningitis occurs almost exclusively among young infants and highly immunocompromised children. It is the leading cause of meningitis among preterm infants and equal to group B streptococcus.^{19,119} *E. coli* meningitis frequently results in intensive

care, severe neurologic impairment, and high mortality, at 34%, 21%, and 14%, respectively.^{48,49} Twenty-eight percent of infants have a concurrent UTI and are older than 6 days of life.⁴⁸ Concurrent bacteremia is present in up to 81% of infants.

Peritonitis

Peritonitis in children is most typically a complication of appendicitis. Intestinal perforation is an infrequent cause in children. Overall it is a rare entity in children, in contrast to adults. *E. coli* accounts for more than 50% of bacterial peritonitis in children, with 60% of the infections being polymicrobial.²⁵

Pneumonia, Endocarditis, and Osteomyelitis

E. coli is an infrequent cause of infections of the lungs, heart, and bones. Pneumonia may arise from oropharyngeal or hematogenous sources and endocarditis through hematogenous spread after translocation of bacteria from the intestinal tract or following urosepsis. Osteomyelitis is most frequently hematogenous after intestinal translocation or urosepsis but also may occur after traumatic injuries and direct inoculation into areas proximal to bone.

PATHOGENESIS

ExPEC produces a wide variety of invasive infections outside of the gastrointestinal tract, including those of the urinary tract, bloodstream, and central nervous system (CNS). ExPEC is a normal commensal organism in the enteric and genital tracts, and colonization alone does not have any measurable consequence to individuals harboring these strains. ExPEC colonizes through oral-fecal transmission where food may be contaminated, through cross-transmission between humans, or, as more recently described, through transmission between domesticated animals such as cats and dogs.⁵² Sexual transmission of ExPEC also has been shown to occur, with male partners appearing to transmit

ExPEC bearing virulence gene characteristics typical of those producing UTIs to their female partners.²⁷ The relative frequency of acquisition of ExPEC by oral-fecal and sexual routes is not clear at present.

ExPEC infections occur after bacteria invade sterile sites such as the urinary tract or the bloodstream from commensal reservoirs such as the enteric tract and vagina. When the immune system is unable to limit the spread of bacteria, invasive infections such as UTI, bacteremia, meningitis, and, more rarely, pneumonia or osteomyelitis may occur.

Urinary Tract Infection

ExPEC is the leading cause of UTI,²⁸ and UTI may precede more invasive infections of the bloodstream, bones, heart, and CNS. ExPEC colonizing the periurethral area may be introduced into the urethra and ascend through the urinary tract. The infection may involve only the urethra (urethritis), but most commonly involves the bladder, resulting in cystitis. More advanced infections may ascend through the ureters to the kidneys, resulting in pyelitis, pyelonephritis, or pyelonephrosis. Anatomic variation or defects, such as voiding dysfunction and vesicoureteral reflux, increase the risk for lower tract and upper tract UTI.³¹

Infrequently ExPEC UTI may occur through hematogenous spread in which bloodstream organisms infect the kidneys and are subsequently isolated from the urine in a descending infection. This may occur during bacteremia after organisms have translocated from the enteric tract. Perinephric abscesses may be the sole consequence of hematogenous infection of the urinary tract.

The specific host and bacterial factors that favor transition from the external genital region into the urethra remain poorly understood in the prepubescent, non-sexually active child. After the initiation of sexual activity, UTI rates increase.²⁸ Spermicides and intercourse are both associated with an increased risk for UTI in women, primarily through promotion of ExPEC in the vagina and mechanical introduction of bacteria into the female urethra, respectively. The size of the inoculum necessary to start an infection in humans is not well understood and is likely overestimated in animal models.

Many of the molecular events during ExPEC cystitis have been elucidated through animal and human studies (Fig. 103.1). ExPEC produces numerous virulence factors that persist in the urinary tract (Table 103.3). Once in the urinary bladder, ExPEC adheres to the bladder epithelium to initiate an infection. Attachment is essential because micturition is a potent host defense to flush the bacteria out of the organ.¹³¹ Type 1 pili, fibrous extensions from the bacteria with adhesive tips, have been established as a major *E. coli* factor promoting adherence to the bladder epithelium. On attachment of ExPEC to the apical surface of the bladder epithelium via type 1 pili, ExPEC can invade into bladder epithelial cells through a variety of routes, including lipid rafts and caveolin, clathrin-coated pits, and fusiform vesicles.^{8,24,59} Within the epithelium, ExPEC may persist long term in late endosomes^{82,83} or escape into the cytosol of the epithelial cell and form intracellular bacterial communities (IBCs), biofilm-like structures with bacteria enmeshed in type 1 pili, aggregative antigens, and polysaccharide capsules.^{3,4} From the IBC state, bacteria may amass and escape as long filaments, only to bind to more bladder epithelial cells and reinvade naïve epithelium.^{54,55}

ExPEC isolates from children with pyelonephritis are more likely to produce P pili, hemolysin, and cytotoxic necrotizing factor (CNF-1) and be serum resistant than cystitis strains or commensal isolates.^{21,49} In the kidneys, ExPEC uses P pili and type 1 pili to adhere to the renal tubule epithelium and persist in the kidney.^{68,77} Local toxin production, including hemolysin, CNF-1, and Sat, damage the epithelium and may permit bacterial penetration and translocation across the border into the adjacent capillary system.^{76,116} The toxins also may inhibit infiltrating granulocytes and limit their capacity to contain the infection.¹⁸

In response to acute infection of the bladder, the lipopolysaccharide-recognition receptor Toll-like receptor 4 (TLR4) is triggered by ExPEC, initiating a signal cascade that results in proinflammatory events, including the expression of cytokines interleukin (IL-6), IL-8, and granulocyte-macrophage colony-forming unit (GM-CSF).^{41,118} Neutrophils and macrophages are recruited into the bladder to assist in clearing the infection.^{65,133} The superficial bladder epithelium is also shed in the process of exfoliation, resulting in elimination of attached and invasive

FIG. 103.1 Pathogenesis of extraintestinal pathogenic *E. coli* (ExPEC) urinary tract infection. ExPEC produces lower and upper tract infection. In the bladder, *E. coli* adheres to the bladder epithelium by using adherence factors such as type 1 pili (*T*, lower right circle). ExPEC can invade the epithelium, replicate, and reemerge as filamentous bacteria (*F*). Infection of the bladder results in a strong inflammatory response (lower left circle) involving production of antimicrobial peptides (*AP*), neutrophil infiltration (*N*), and exfoliation, or sloughing, of the epithelium (*E*). ExPEC produces a capsule (*C*) to protect against the innate immune response. ExPEC can migrate up the ureters (middle left circle) against urinary flow using flagella (*M*). In the kidneys, ExPEC produces P pili (*P*) and other adhesive factors to bind to the renal epithelium, where biofilms (*B*) may be formed. An inflammatory response includes neutrophils (*N*) and other factors such as complement and antimicrobial peptides. From the kidney tubules, ExPEC may also produce toxins (*TX*; upper right circle), damaging the local epithelial and endothelial borders to invade capillaries and disseminate in the bloodstream, producing bacteremia.

intracellular ExPEC. Microscopy of urine from young women with acute cystitis revealed leukocytes and exfoliated bladder epithelial cells, including filamentous ExPEC and cells harboring IBC.¹⁰⁷ In animal studies, the clearance of ExPEC is incomplete even with the application of antibiotics, resulting in chronic latent intravesical infection, predicted to be a reservoir for some recurrent infections.^{83,111}

The determinants that balance acute inflammatory infections and ASB are not fully known. ASB and cystitis isolates have reduced virulence gene numbers relative to strains causing pyelonephritis.^{10,122} Despite similar known virulence gene content in cystitis strains of ExPEC, a prototypic ASB isolate of *E. coli* has been previously shown to have reduced virulence factor gene expression in contrast to cystitis isolates, and ASB isolates may outcompete cystitis strains for growth in urine.¹⁰⁶ The host response to bacteria within the urinary tract is likely to be important to the development of ASB. Children with reduced TLR4 expression have been shown to have an increased risk for ASB.¹⁰⁰

Bacteremia

ExPEC are frequent causes of bacteremia secondary to translocation from the intestinal tract into the bloodstream. This frequently occurs in patients with loss of intestinal epithelial barrier integrity or compromised immunity. ExPEC produces protective factors that favor survival in serum, including polysaccharide capsules known to inhibit complement deposition, opsonization, and phagocytosis by granulocytes.^{12,47,108} Toxins such as hemolysin A and CNF-1 have roles in inhibiting phagocyte function,^{18,99} thus limiting ExPEC clearance. ExPEC also responds to the bloodstream environment by downregulating factors that may stimulate immunity or promote phagocytosis such as the adhesive factor type 1 pili.

Critical metabolic pathways are necessary for successful dissemination of ExPEC in bloodstream infections. Sialic acid usage and iron acquisition have been previously shown to be essential for ExPEC survival during disseminated infection.¹¹⁵

TABLE 103.3 Representative Extraintestinal *Escherichia coli* Virulence Factors

Functional Category	Virulence Factor	Role	References
Adhesin	Type 1 pili (<i>fim</i>)	Adherence to urinary tract epithelium, particularly in bladder; lectin-recognizing mannosylated glycoproteins	50, 51, 60
	P pili (<i>pap/prf</i>)	Adherence to urinary tract epithelium, particularly in bladder; lectin-recognizing glycolipids	68, 74, 101, 125
	S pili (<i>sfa/foc</i>)	Bind to α -sialyl-2,3- β -galactoside found in urinary tract and central nervous system	131
	Auf pili	Expression in urinary tract but unknown function	15
	Dr adhesins	Examples include Dr and Afa I-IV; binding to decay-activating factor	33, 91
	TosA	Repeats-in-toxin (RTX) protein; adherence to renal tubular cells	127
	UpaB	Autotransporter-type adhesion; binding to extracellular matrix proteins	2
Invasin	Tsh	Serine protease-type autotransporters; associated with pyelonephritis strains	42
	IbeA	Invasion of the brain endothelium	52, 74
Toxins	OmpA	Outer membrane protein A	88
	HlyA	α -Hemolysin	79
	Cyclomodulins	Examples include cytolethal distending toxin (CDT-1) and cytotoxic necrotizing factor 1 (CNF-1)	22
	Sat	Serine autotransporter	37
Protectins	Groups II and III polysaccharide capsules	K1, K2, and K5 capsules, among others	3, 5

Immune regulators	TcpC	Immunomodulator	74
	SisA/B	Inflammation suppressors	72
Other	DsdA	D-Serine deaminase	39
	Flagella	Motility	67, 132
	Cellulose	Biofilm formation	90

Meningitis

ExPEC disseminates from mucosal surfaces through the bloodstream to the CNS. Neonatal animal models have suggested that ExPEC disseminates to the CNS within macrophages and that dissemination depends on nitric oxide production.⁷⁸ The burden of organisms during bacteremia correlates with the likelihood of developing meningitis in both infant and adult animal models.⁶³ At the blood-brain barrier (BBB), ExPEC transverse the brain microvascular endothelial cells by first binding and invading the cells through actin rearrangement and transcellular traversal of the barrier.⁶³ Type 1 pili and OmpA (Table 103.4) are key adhesive factors mediating the initial interaction between *E. coli* and the vasculature via gp96 and CD48, respectively.^{62,97} The *E. coli* factor IbeA has been shown to enhance brain microvascular endothelial cell invasion.^{29,98} K1 polysaccharide encapsulation, common among ExPEC causing neonatal meningitis, prevents late endosome-lysosomal fusion and thus killing of intracellular *E. coli*, whereas lack of encapsulation results in bacteria proceeding through early to late endosomes and lysosomal fusion with eventual degradation of the bacteria-containing vacuoles.⁶⁴ The consequence of brain endothelial cell invasion by *E. coli* is cytokine release such as the proinflammatory factor IL-8, brain endothelial cell apoptosis, BBB dysfunction, and increased permeability, ultimately leading to encephalopathy.⁶³

CLINICAL PRESENTATION

Urinary Tract Infection

Acute UTI with *E. coli* is associated with dysuria, urinary frequency, urgency, and often cloudy or odorous urine. Cystitis typically has low-grade fever or no elevation in temperature and may include anterior abdominal or pelvic pain or pressure. In contrast, *E. coli* pyelonephritis includes flank or lower back pain, and high fever, often higher than 38.9°C (102°F). Pyelonephritis may also include chills, sweats, rigors,

TABLE 103.4 Susceptibility to Antibiotic-Class Representative Agents Commonly Used in the Treatment of Urinary Tract Infection and Invasive *Escherichia coli* Infections

Antibiotic ^a	Resistance (95% CI)	Reference
Ampicillin/amoxicillin	53.4% (46–60.8%)	14
Amoxicillin-sulbactam	8.2% (7.9–9.6%)	14
Trimethoprim-sulfamethoxazole	23.6% (13.9–32.3%)	14
Nitrofurantoin	1.3% (0.8–1.7%)	14
Ciprofloxacin ^c	2.1% (0.8–4.4%)	14
Levofloxacin ^c	9%	Unpublished ^b
Ceftriaxone	5%	Unpublished ^b
Gentamicin	8%	Unpublished ^b

^cUS Food and Drug Administration–approved for complicated *E. coli* urinary tract infections.

nausea, vomiting, and headache. In patients with perinephric abscesses or intrarenal necrosis, the patient may have pleuritic chest pain from irritation of the diaphragm, and a flank mass may be palpable on physical examination. Bacteremia and urosepsis may develop secondary to pyelonephritis, especially among patients with diabetes, urinary tract abnormalities, urinary obstruction, or pregnancy. Pyelonephritis with and without urosepsis must be differentiated from intraabdominal

processes, including appendicitis, psoas abscess, ruptured ovarian cyst, and ectopic pregnancy.

E. coli UTIs are not easily distinguished symptomatically from the syndromes caused by other organisms, including *S. saprophyticus* in the female adolescent, *K. pneumoniae*, *P. mirabilis*, or group B streptococcus.

Bacteremia and Sepsis

Bacteremia by *E. coli* is not readily distinguished in signs and symptoms from bloodstream infections produced by other gram-negative bacteria. Children may have fever, fatigue, lethargy, or irritability. Nausea and vomiting may accompany bloodstream infections. Some children may have a diffuse erythematous rash and, in the case of sepsis, generalized edema. Tachycardia may occur in the presence and absence of fever. Urine output may be diminished accompanying renal failure in cases of severe infection.

Meningitis

Neonates with *E. coli* meningitis present with general nonspecific features, including fever, vomiting, irritability, and failure to thrive. In advanced circumstances, neurologic signs, including apnea, seizures, decreased muscular tone, and ocular or limb palsies, may be present. Jaundice may accompany the presentation. In the infant older than 3 months, nuchal rigidity and a tense fontanelle may be part of the presentation. Acute *E. coli* meningitis in the older child is accompanied by headache, nausea, vomiting, lethargy, confusion, and fever. Neurologic features such as seizure or focal symptoms may accompany *E. coli* meningitis. The clinical presentation of *E. coli* meningitis overlaps with other etiologies of meningitis. Acute *E. coli* meningitis must be differentiated from other processes, including seizure disorder, brain abscess, aneurysm, sepsis, and, in the case of the neonate, tetanus.

E. coli meningitis is a rare complication of neurosurgical procedures. The clinical presentation may not be different from that of acute meningitis in the nonsurgical patient. However, infectious meningitis must be differentiated from other infectious and noninfectious complications of surgery.

Intraabdominal Infection

E. coli produces cholecystitis and cholangitis associated with right upper quadrant pain, fever, and jaundice. In advanced cases, bacteremia and sepsis may complicate the infections. Both infections are associated with high fever, typically above 38.9°C (102°F). Cholangitis is accompanied by chills and sometimes hepatic abscess. Children with *E. coli* cholecystitis or cholangitis develop right upper quadrant pain, fever, and jaundice. In severe cases, hypotension and confusion also develop. Cholecystitis manifests with fever (>38.9°C [102°F]). Cholangitis manifests with fever (>38.9°C [102°F]), shaking chills, and right upper quadrant pain and can be complicated by hepatic abscess. Other infectious etiologies may bear resemblance to *E. coli* intraabdominal infection, including *Klebsiella* spp., enterococcus, and, with appropriate exposure histories, amoebic abscess or *Echinococcus* spp.

E. coli also may cause intraabdominal abscesses with and without peritonitis. Abscess alone may be associated with low-grade fever and nonspecific abdominal pain, as well as occasional malaise and anorexia. Peritonitis is associated with higher fever and rebound pain. In severe cases, septic shock may accompany peritonitis. Patients with *E. coli* intraabdominal abscesses may have low-grade fever, but the spectrum of clinical presentations ranges from nonspecific abdominal examination findings to frank septic shock. Peritonitis manifests as localized pain with rebound and fever. Abdominal abscess with *E. coli* are often polymicrobial with anaerobes, gram-negative bacilli, and enterococci.

Pneumonia

Children with *E. coli* pneumonia typically present with a febrile illness, shortness of breath, tachypnea, increased respiratory secretions, and rales and crackles with auscultation. *E. coli* pneumonia may be ventilator-associated and bacteremia-associated. *E. coli* is a rare cause of community-acquired pneumonia in a child with otherwise normal immune defenses. *E. coli* pneumonia is difficult to distinguish clinically from other bacterial pneumonia.

DIAGNOSIS

General

The definitive diagnosis of ExPEC infection is isolation of the organism from a sterile site such as urine, blood, or cerebrospinal fluid (CSF). Isolation from sputum or wounds is also indicated in some circumstances, such as pneumonia and abdominal infections, respectively. In these circumstances, recovery of the bacterium must be regarded in the context of the patient's clinical presentation to determine if the isolation of the organism is compatible with infection or represents colonization.

E. coli is readily isolated from a wide variety of clinical samples at 37°C (98.6°F) and aerobic conditions.⁴⁰ Nonselective and selective media, including MacConkey agar, will isolate *E. coli*. Approximately 90% of isolates are lactose fermenting, and approximately 99% produce indole, making this an optimal biochemical test for the identification of *E. coli*.⁸⁵ *E. coli* does not typically produce pigments, but many isolates are β -hemolytic, although a significant percentage from sites such as the urinary tract may not display β -hemolysis on blood agar.

Urinary Tract Infection

For suspicion of UTI, a urine dipstick test may be performed to rapidly determine if the patient has pyuria or bacteriuria based on the detection of leukocyte esterase and nitrites, respectively. Definitive diagnosis is based on urine culture results. The specimen should be collected from a midstream clean void in children old enough to provide such a sample or by straight sterile catheterization in younger children. A contaminated specimen and asymptomatic colonization must be differentiated from infection based on clinical symptoms and signs, as well as the urinalysis consistent with inflammation. In cases of infection, pyuria usually is present. In urinalysis, leukocyte esterase and nitrite each have a sensitivity of 0.88 and a false-positive rate of 0.05. Bacteria identified by Gram stain on noncentrifuged samples have a sensitivity of 0.93 and false-positive rate of 0.05. White blood cells alone have poor sensitivity and increased false-positive rate.³⁴

Routine screening of the urine for cure after antibiotic therapy and screening for asymptomatic colonization are not recommended because screening produces a large number of false-positive results and does not alter rates of renal scarring.^{58,61}

Imaging studies may be indicated in some patients to assist in making a diagnosis of *E. coli* infection, determining the necessity for an interventional procedure, or assessing the prognosis. For UTI, renal ultrasonography, computed tomography (CT), or dimethylsuccinic acid scans may be indicated to evaluate the kidneys and look for any other source of abscess, stones, or obstruction. Vesicoureterogram may be indicated for the diagnosis of vesicoureteral reflux, which may predispose a patient to pyelonephritis.

Other Infections

Recovery of the organism in contaminated sites, such as sputum and wounds, must be analyzed in the context of the patient's clinical state to determine if it represents colonization or infection. Recovery from sterile sites, such as the CSF, should be considered diagnostic of infection.

Lumbar puncture and a CSF culture for *E. coli* will establish the diagnosis of acute *E. coli* meningitis. Before culture data are available, CSF parameters alone will not be specific for *E. coli* infection. Elevated protein, depressed glucose, and the presence of leukocytes with a neutrophilic predominance may be present. Before culture information is available, Gram stain may reveal gram-negative bacilli without being solely indicative of *E. coli*. Justification for a lumbar puncture and analysis must be made based on indications for possible CNS infection, including a positive blood culture, altered behavior, and abnormal neurologic signs, such as seizures.

Patients with pneumonia should have blood cultures and sputum Gram stain and culture performed. The results of a Gram stain of the sputum help differentiate a good specimen (i.e., many polymorphonuclear [PMN] leukocytes and few squamous epithelial cells) from a bad specimen (i.e., few PMN leukocytes and many squamous epithelial cells). Culture should be obtained before antibiotic therapy is initiated.

Additional studies may be indicated for non-UTI ExPEC infections. In pneumonia, chest radiography or CT is indicated. In cholecystitis

and cholangitis, ultrasonography or CT of the right upper quadrant is indicated. For suspicion of intraabdominal abscess, abdominal and pelvic ultrasound or CT may be indicated.

TREATMENT

General

Therapy for ExPEC infections depends on the site and severity of infection. The choice of antibiotics must be determined on the basis of local regional antibiotic susceptibilities, site to which the antibiotic is to be delivered, and appropriateness and tolerance of oral or parenteral agents.

Urinary Tract Infection

Determination of therapy for UTI is first contingent on the appropriateness of oral therapy or intravenous antibiotics. Most community-acquired UTIs may be treated with oral therapy, assuming that antibiotic resistance that would preclude therapy with an available oral agent is not suspected, the child is able to tolerate oral therapy (e.g., not vomiting), and the child does not have underlying urinary tract anomalies or other comorbidities such as diabetes mellitus, renal transplantation, systemic lupus erythematosus, or other conditions. Infants with UTI in the first month of life should be given parenteral antibiotics at the start of their treatment because of the challenge of differentiating lower and upper tract infections, the high prevalence of concomitant bacteremia (~10%), and concurrent urinary tract pathology, including posterior urethral valves, obstructed duplex systems, and high-grade vesicoureteric reflux with serious metabolic disturbance, such as hyperkalemia and hypernatremia. Furthermore past trials have excluded young infants, leaving no specific data to further guide management of UTI in this group.

The duration of therapy for cystitis should be 5 to 7 days, although pediatric-specific data regarding sufficient minimum duration of therapy are not available. Caution must be taken because it may be difficult in the young child to differentiate lower and upper urinary tract involvement, especially given that fever is a typical presenting symptom suggesting upper tract involvement. Typical therapy entails oral trimethoprim-sulfamethoxazole (TMP-SMX), trimethoprim alone, cephalexin, amoxicillin-clavulanate, or nitrofurantoin. The fluoroquinolone ciprofloxacin is not approved for use in children except for complicated *E. coli* UTI.

Prior research has indicated that oral therapy for pyelonephritis using the cephalosporins cefixime and ceftibuten or amoxicillin-clavulanate is effective in treating acute infections and does not result in a significant increase in renal scarring in contrast to initial parenteral therapy.^{44,81,86} Pyelonephritis should be treated for a longer duration of 10 to 14 days. In children who are not candidates for initial oral therapy, 2 to 3 days of parenteral therapy should be provided until the child is able to tolerate an oral agent. However, no difference in renal scarring was identified in children receiving initial parenteral therapy before oral therapy in contrast to children receiving oral therapy for the entire course.⁸⁶ Longer initial intravenous therapy (8 days vs. 3 days) also was not shown to decrease renal scarring.¹² The combined duration of parenteral and oral therapy should then be the same as for children receiving only oral therapy.

E. coli UTI complicated by perinephric or intrarenal abscess may require surgical drainage and longer therapy. Ultrasound evaluation may be indicated before discontinuation of therapy.

Antibiotic prophylaxis has been used to prevent recurrent UTI for the primary purpose of reducing the risk of renal scarring and long-term renal insufficiency. The role of prophylactic antibiotics for the prevention of UTI has changed in recent years as more studies indicate they do not provide significant protection from recurrent infections and in particular renal scarring^{30,80,92,95} and demonstrate that prophylactic antibiotics, particularly β -lactams like amoxicillin and cephalosporins, may result in subsequent infections with resistant organisms.^{36,84} Even the most recent data from the largest randomized controlled study yet of children with VUR demonstrated no reduction in renal scarring attributable to daily prophylaxis (8.2% vs. 8.4%, with and without prophylaxis).⁴³ Prophylaxis did reduce recurrent UTI (14.8% vs. 27.4%, with and without prophylaxis) with a number needed to treat of 8 and 2 years of therapy, although an increase in antibiotic-resistant organisms was noted in a

number of children. Exceptions may be for children with high-grade vesicoureteral reflux grades IV and V awaiting surgical interventions, for whom the benefits of daily antibiotic prophylaxis to prevent recurrent UTI and renal scarring may outweigh the risks that include cost and the emergence of multidrug-resistant organisms. TMP-SMX or nitrofurantoin may be considered in these circumstances.

Other Infections

The treatment of invasive infections for *E. coli* should entail parenteral antibiotics of the appropriate spectrum, accounting for local resistance patterns and, in the case of empirical coverage, for other possible etiologic agents. Two antimicrobials with independent mechanisms of action such as a β -lactam and an aminoglycoside should be considered in patients at risk for multidrug-resistant *E. coli* infections. Past hospitalization and antibiotic exposure are among the risk factors for multidrug resistance.

The treatment of *E. coli* bloodstream infections is generally 10 to 14 days. Serious consideration should be given to the removal of central venous catheters in the presence of a high degree of suspicion that the catheter may be involved or responsible for the infection, although mixed data exist for the necessity of catheter removal.^{6,16,38,93} *E. coli* meningitis should be treated for a minimum of 21 days or 14 days after obtaining a negative CSF culture, whichever is longer.⁹⁶ Parenteral therapy is indicated for both bloodstream infection and meningitis. Treatment of *E. coli* meningitis should include an agent with known penetration of the BBB, for example, an advanced cephalosporin such as cefotaxime or a carbapenem such as meropenem, as well as an aminoglycoside, until full antibiotic susceptibilities are available.

Antibiotic Susceptibility

Specific antibiotic susceptibility data for pediatric *E. coli* isolates in North America are severely lacking. However, the antibiotic resistance of *E. coli* causing invasive infections among the population as a whole, particularly UTI, has undergone major shifts over the past decade. Previously *E. coli* was widely susceptible to a range of antibiotics, but, in the past decade, resistance has increased in prevalence (see Table 103.4). Susceptibilities of *E. coli* to cephalexin and cefixime, often employed in treating pediatric *E. coli* infections in the outpatient setting, are notably unavailable. Antibiotic resistance to ampicillin, amoxicillin, and TMP-SMX is now broadly distributed. Neonates delivered to mothers treated with ampicillin for the prevention of group B streptococcus infection have an increased risk for ampicillin-resistant *E. coli* early-onset sepsis.⁹ Furthermore multidrug resistance is common. Of the *E. coli* resistant to TMP-SMX, they are twice as likely to be resistant to ampicillin and 33 times more likely to be resistant to the fluoroquinolones and nitrofurantoin.¹³⁴

Risk factors associated with infection with extended-spectrum β -lactamase (ESBL)-producing *E. coli* include underlying illness and hospitalization in the previous 3 months.¹²⁶

OUTCOMES

General

Outcomes of *E. coli* infections depend on the degree of invasiveness and status of the host immunologic defenses.

Urinary Tract Infection

Cystitis has the lowest morbidity, mostly incurred in terms of socioeconomic costs and emergence of antibiotic resistance. In contrast, pyelonephritis and other renal infections require more extended antibiotic therapy, incurring more cost and lost time from school and work. Furthermore renal infections may result in progressive renal scarring with the concern for loss of renal function and early renal insufficiency. In some circumstances, particularly in young children, children with anatomic variations of the urinary tract and those with diabetes, UTI may precede bloodstream infections.

Other Infections

The mortality rate for early-onset and late-onset sepsis in neonates has been previously shown to be approximately 15% and 9%, respectively.⁵²

In infants with very low birth weight (<1500 g) the odds ratio of death with early-onset and late-onset sepsis was 1.45 and 1.30, respectively, with *E. coli* contributing to this degree of risk.⁴⁶ Among older children with central venous catheter-related *E. coli* bloodstream infections, the mortality rate is approximately 7% despite appropriate antibiotic therapy, with parenteral nutrition and mechanical ventilation being predictors for poor outcome.¹⁶

In a 25-year retrospective study of neonates with meningitis in a tertiary medical center, of which *E. coli* was one of the top three pathogens, approximately 14% died and 40% had significant morbidity, including seizures and hearing loss.⁷²

Diarrhea-Causing and Dysentery-Causing
Escherichia coli

Jorge J. Velarde • James P. Nataro

Escherichia coli has been long recognized as the most common facultative anaerobe in the human gastrointestinal tract. Virtually all *Homo sapiens* (and most other mammals) harbor this bacterium. Yet within the *E. coli* biomass lurk highly evolved pathogenic subtypes that have adapted themselves to a new niche—human pathogenicity. These pathotypes may prefer the gastrointestinal tract, the genitourinary tract, or disseminated sites (including the meninges)—the last almost exclusively in neonates. This chapter focuses on *E. coli* associated with enteric infections.

The first implication of *E. coli* with diarrhea occurred more than 75 years ago, when Adam³ postulated the existence of a group of “dyspepsia” *E. coli* responsible for neonatal and infantile diarrhea. In the 1940s, Bray reported that many, but not all, *E. coli* from severe infant diarrhea cases in summer agglutinated with antiserum prepared from a diarrheal isolate, whereas *E. coli* organisms from other sources did not.¹³ The isolate used by Bray to develop the antiserum was later serotyped by the Kauffman scheme as O111:B4, one of the now classic serogroups of enteropathogenic *E. coli* (EPEC) (Table 104.1). Although this initial description was made possible by serologic fingerprinting, the advent of molecular biology rapidly produced a plethora of reports describing the several discrete *E. coli* pathotypes.

CAUSATIVE ORGANISMS

Six distinct diarrheogenic pathotypes are recognized currently on the basis of clinical, biochemical, and molecular or genetic criteria (Table 104.2) as follows:

1. Enterotoxigenic *E. coli* (ETEC), a major cause of traveler’s diarrhea and infant diarrhea in developing countries, elaborates the heat-stable enterotoxin, the heat-labile enterotoxin, or both and causes infection of the small intestine.
2. EPEC, the original pathotype defined by Bray,¹³ causes infant diarrhea in less-developed countries. The bacteria induce a characteristic attaching and effacing lesion in the small intestine. Classic EPEC requires the chromosomally encoded locus of enterocyte effacement (LEE) and a high-molecular-weight virulence plasmid termed EPEC adherence factor (EAF) plasmid.
3. Enterohemorrhagic *E. coli* (EHEC) causes outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome (HUS) in temperate climates. The essential virulence factor is the Shiga toxin, which circulates through the bloodstream and acts by inhibition of protein synthesis in the target cell.

4. Enteroinvasive *E. coli* (EIEC) is an unusual cause of diarrhea and dysentery. It is similar to *Shigella* epidemiologically and pathogenetically and shares similar virulence genes.
5. Enteragggregative *E. coli* (EAEC) causes diarrhea in individuals of all ages in industrialized and less-developed countries and in travelers. The organism adheres to the intestinal mucosa and secretes several enterotoxins and cytotoxins.¹⁴²
6. Diffusely adherent *E. coli* (DAEC) is a highly heterogeneous pathotype; its association with diarrhea is controversial. The epidemiologic scenario for this organism has not been well elucidated.

TRANSMISSION AND EPIDEMIOLOGY

Diarrheogenic *E. coli* strains are worldwide in distribution. The route of infection is fecal-oral, predominantly via contaminated food and water, although person-to-person transmission may occur with EHEC and possibly EPEC in infants.¹⁷⁵ As discussed subsequently, environmental contamination by EHEC is an emerging problem in industrialized countries, whereas ETEC continues to be ubiquitous worldwide. Table 104.3 lists the age-specific predilections of the various *E. coli* pathogens.

Enterotoxigenic *Escherichia coli*

The infectious dose for ETEC is approximately 10^8 bacteria.⁶⁹ The incubation period is 14 to 50 hours.¹⁷¹ Transmission typically occurs via contamination of food and water,²³² and person-to-person transmission is thought to be uncommon due to its high infectious dose. In developing countries, contamination of food and water sources occurs commonly.²⁰⁸ ETEC has been detected in the United States in numerous food samples, including cheese, hamburger, sausage, and seafood.^{116,159,232} A domestic US outbreak of diarrhea at Crater Lake National Park in Oregon was traced to ETEC organisms in the water supply.²²⁶ Additional outbreaks in developed countries have been described.^{47,76,152,199} Because large numbers of organisms are required for experimental infection, transmission probably would require multiplication of the inoculum within the vehicle, which probably contributes to the well-documented propensity of ETEC infection to occur in warm months.²⁰⁸

ETEC is a major cause of diarrhea in infants and children in the developing world.^{92,208} The incidence typically increases during the first 6 months of life and decreases after 2 years. ETEC has been estimated to cause approximately 20% of diarrheal episodes in the developing world,²⁰⁸ although this percentage varies substantially by location. A

study in rural Egypt found that ETEC accounted for 66% of all first episodes of diarrhea, with an incidence of 1.7 episodes per child-year during the first 6 months of life and 2.3 during the second 6 months.²¹¹ In Tehran, researchers found that ETEC could be isolated from 15.5% of patients younger than 5 years old with diarrhea.²³⁶ The prevalence was 18% in Bangladesh,²⁰⁷ 33% to 37.5% in Mexico,^{56,75} and 20.5% among children with diarrhea in Nicaragua.²⁸⁸ A study in Hanoi found,

however, that only 2.2% of diarrheal episodes could be attributed to ETEC.¹⁸² Prevalence was 9.2% in a study in the Brazilian northeast,¹⁸⁵ and the frequency in Mongolia²⁴⁰ was similarly low. A large multicenter case-control study of moderate-to-severe diarrhea among children under 5 years of age at seven sites in sub-Saharan Africa and south Asia implicated ETEC consistently among the top five etiologic pathogens.¹³⁵ In this study, STh-producing strains accounted for the large majority of attributable cases.

ETEC disease is primarily a childhood problem, with the incidence decreasing after the child reaches 5 years of age.^{207,208} After infection with a particular ETEC strain, the host is resistant to disease but still may excrete the organism asymptotically, a characteristic that contributes to the environmental burden.^{175,266} Adults still may be susceptible to ETEC diarrhea.^{92,208} In a study of elderly individuals in Dhaka, Bangladesh, researchers found that 13% of adults older than 60 years with diarrhea were noted to have ETEC.⁷⁷ Although the incidence of ETEC diarrhea decreases after age 5 years, the incidence seems to increase again in patients older than 15 years, and 25% of ETEC infections are seen in adults.^{207,208}

ETEC is the most common cause of traveler's diarrhea, typically accounting for approximately 30% to 40% of cases, except in southeast Asia where it has been found to account for approximately 7% of cases.^{2,120,243,248} Illness is acquired by ingestion of contaminated food or water. The diarrhea is acute and watery and typically resolves spontaneously without severe limitation of activities.²

EPEC organisms are extremely diverse, and children in endemic areas experience multiple infections. The basis of immunity, which increases with repeated exposure, is unknown.²⁶⁶ Strains producing heat-stable enterotoxin cause more severe disease than strains producing only heat-labile enterotoxin, and the former is not immunogenic. Colonization of the small intestinal mucosa is mediated by surface fimbriae termed *colonization factor antigens*, which are immunogenic and may elicit some element of protective immunity.²¹² Despite the existence of more than 25 known colonization factor antigens (or CFAs), a few are overrepresented among clinical isolates;^{184,231,249,288} in a study from Bangladesh for instance, seven colonization factor antigens constituted more than 75% of the colonization factor antigens isolated.²⁰⁷ In an analysis of multiple studies, Wolf²⁹⁶ suggested that most EPEC express colonization factor antigens I, II (CS1, CS2, CS3), or IV (CS4, CS5, CS6). A recent study looking at more than 360 EPEC isolates from around the world also suggested that there are multiple lineages with CFA and associated toxin profiles that appear to be stable over time.²⁹¹ Of note, in some epidemiologic studies, more than 50% of strains do not express known colonization factor antigens.^{249,250} This may be second to the presence of colonization factor antigens that are as yet unrecognized.¹⁷⁰ EPEC is predominantly an infection of warm weather months in endemic areas, coincident with conditions promoting bacterial replication in the environment. Some sites report that a second peak occurs after the rainy season.^{207,208}

Enteropathogenic *Escherichia coli*

Neter and associates¹⁸¹ first coined the term EPEC to denote a group of *E. coli* serotypes associated with dramatic and highly lethal nursery outbreaks of diarrhea in the United States and the United Kingdom (see Table 104.1). We now recognize that these serotype antigens serve as surrogate markers for a package of chromosomal and plasmid-borne virulence genes, which together orchestrate enteric pathogenesis.^{137,179,299} The epidemiology of EPEC has changed since its original description was provided. Gone are the lethal outbreaks formerly reported in industrialized countries, to be replaced by sporadic endemic disease in resource-poor countries. The infection retains its dramatic predilection for infants and children younger than 24 months, is rarely seen in older children and adults, and is not a cause of traveler's diarrhea.^{55,56,93,135,281} The basis of this age-dependent incidence is unknown.

Globally, EPEC is among the most common causes of infant diarrhea.^{55,56,93,188,189,221} EPEC has a propensity to cause persistent infection and wasting, suggesting that its burden may comprise more than simple dehydration. Breast-feeding offers some protection against EPEC because of the presence of immune factors and oligosaccharides that inhibit adherence of EPEC to epithelial cells.⁵⁸ In industrialized countries such as the United States, EPEC generally is no longer considered to be a cause of endemic diarrhea, although EPEC may be present in infants immigrating from or visiting resource-poor settings. Rare indigenous cases may occur.⁹⁵ In an outpatient setting in the United States, two of 147 cases of nondysenteric acute diarrhea were caused by EPEC.³⁸ In 166 Swiss children admitted to hospitals with diarrhea, 13 (7.8%) had EPEC isolated from stool cultures.⁷⁴

As noted previously, EPEC strains of the classic serotypes (also known as typical EPEC) require the chromosomal locus of enterocyte effacement (LEE) and the EPEC adherence factor plasmid (encoding the bundle-forming pilus, or BFP) to cause diarrhea. Controversy exists over whether so-called atypical EPEC (which are positive for the locus of enterocyte effacement and negative for BFP) are a cause of diarrhea.¹⁷² Several studies and outbreak descriptions suggest there is a relationship.^{4,52,220,300} Other studies, however, have failed to identify atypical EPEC as a cause of diarrhea.^{135,177} Recent molecular epidemiologic studies have suggested that atypical EPEC may require a chromosomally encoded adhesion factor termed Efa1,^{5,189} which may substitute for the EPEC plasmid-encoded BFP.

Enterohemorrhagic *Escherichia coli*

Since its discovery in 1977, EHEC has emerged as an important and increasingly common human pathogen. Although most occurrences of disease are sporadic and not all occurrences are related to ground beef,²⁷⁶ EHEC is notably carried asymptomatically in cattle and other ruminants,

from whence it can be transmitted widely. The organisms may be excreted by cattle herds, and large outbreaks of human infection have been associated with the ingestion of undercooked hamburger and other foods contaminated directly and indirectly by cattle manure. Careful prospective epidemiologic surveillance in Minnesota revealed an increase in the incidence of EHEC from 0.5 to 2 per 100,000 children younger than 18 years old during the period 1979 to 1988,¹⁵⁵ similar to the incidence of EHEC determined in the state of Washington in the late 1980s: 2.1 per 100,000. Recent data from the CDC FoodNet surveillance network in 2012 indicated current incidence rates in the United States of 1.11 cases of O157 STEC and 1.16 cases of non-O157 STEC per 100,000 population.⁴⁵ In a multicenter study of mild acute diarrhea in outpatients in the United States, five (3.4%) of 147 cases were caused by EHEC,³⁸ a frequency similar to that in Swiss children hospitalized for community-acquired diarrhea.⁷⁴ Very young children are not commonly infected; rather, infection occurs most commonly and severely in children 2 to 10 years old or in the elderly.

Ground beef is identified as the most common source of EHEC infection. Several outbreaks have been associated with fast-food consumption.²¹⁰ In meat-processing plants where bulk ground beef is prepared for the fast-food industry, meat from one contaminated carcass can contaminate and distribute the organisms to a huge number of beef patties. Several other food sources of transmission that have been documented include other beef; produce, including spinach and lettuce; milk; water; and processed foods, including unpasteurized apple cider, mayonnaise, and dry fermented sausage. Person-to-person, cattle-to-person, and waterborne outbreaks have been described. Person-to-person spread as sequelae of point-source epidemics is common.²⁴⁷ Many unusual modes of transmission linked with cattle have occurred and include poorly washed apples dropped in cow pastures and used to make cider, surface water supplies in proximity to areas where cattle graze, spread of aerosolized particles at agricultural fairs, and transmission by contact at petting zoos. Contaminated swimming holes have been implicated in several outbreaks.

A multistate outbreak of O157:H7 EHEC infections associated with the consumption of fresh bagged spinach occurred in the United States in 2006, affecting 26 states and resulting in 205 confirmed illnesses, 103 hospitalizations, 31 cases of hemolytic-uremic syndrome, and three deaths.^{15,39} This outbreak exemplifies the widespread effect of a foodborne outbreak caused by the mass production and distribution of produce.

Hemolytic-uremic syndrome is a not infrequent sequelae of EHEC-associated infection. A review of O157:H7 outbreaks (defined as two or more cases) reported to the Centers for Disease Control and Prevention in the United States from 1982 to 2002 found 350 outbreaks representing 8598 cases, 1493 (17%) hospitalizations, 354 (4%) cases of hemolytic-uremic syndrome, and 40 (0.5%) deaths.²¹⁰ During a large outbreak of *E. coli* O157:H7 infection associated with fast-food restaurant hamburgers on the West Coast of the United States in 1993, of the 732 affected individuals identified, 195 were admitted to the hospital, hemolytic-uremic syndrome developed in 55 (7.5%), and four died.⁹⁵ Investigation of this outbreak showed that small numbers of bacteria (in the range of a few hundred) constituted an infectious dose. Among 93 cases of O157:H7 infection reported in Washington State in 1987, hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura developed in 11 (12%), for an approximate incidence of 0.23 per 100,000.¹⁹⁶

The highest incidence of hemolytic-uremic syndrome occurs in children younger than 5 years, in whom the age-specific incidence ranged from 2.6 to 5.8 per 100,000 in Minnesota,¹⁵⁵ Washington,¹⁹⁶ and Oregon.²²⁴ More recently, improvements in animal processing and public health interventions including detection and investigation of outbreaks has led to a U.S. national decrease in the incidence of hemolytic-uremic syndrome to less than one case per 100,000.⁴³ The incidence of hemolytic-uremic syndrome in Argentina was reported in 2002 as 12.2 per 100,000 children younger than 5 years, which is among the highest reported incidence of hemolytic-uremic syndrome in the world.^{148,219}

In the United Kingdom and the United States, hemolytic-uremic syndrome is associated predominantly with Stx2-producing *E. coli* O157:H7^{155,197}; however, this finding may represent more facile detection of this serotype. In addition, the incidence of non-O157:H7 infections in the United States is increasing (serotypes associated with EHEC

infection are presented in Table 104.1).^{35,122,295} In Argentina, non-O157:H7, Stx2-producing strains are commonly isolated.^{148,219} Similarly, in Australia, other serotypes, especially O111, have been associated with major outbreaks and a significant number of hemolytic-uremic syndrome cases.⁴¹ Many of these serotypes have been implicated in sporadic and outbreak disease in the United States³³ (e.g., an outbreak caused by O104:H21 acquired from contaminated milk⁴²).

Non-O157:H7 EHEC infections have increased in prevalence in the United States and are now known to account for 20% to 50% of all EHEC infections.^{45,122} Although some non-O157 strains are not pathogenic, others have been shown to cause disease as severe as that caused by O157:H7 strains, suggesting that a clinical suspicion for EHEC should be maintained even when testing for O157:H7 is negative.¹²² Non-O157, Stx-producing *E. coli* infection was made a reportable disease in the United States in 2000.³⁵

In 2011, a large, international outbreak of hemorrhagic colitis and hemolytic-uremic syndrome occurred due to a Shiga toxin *E. coli* of serotype O104:H4.¹¹⁷ The outbreak originated in Germany, and was traced to the consumption of contaminated fenugreek sprouts, most likely coming from Egypt. More than 4000 infections were identified among 16 countries, resulting in more than 50 deaths.⁴⁴ Interestingly, the implicated pathogen was an enteroaggregative *E. coli* strain which had become lysogenized with the Shiga toxin-encoding phage. Such strains had previously been identified, and may become an emerging threat.¹¹⁷

Hemolytic-uremic syndrome occurs seasonally in the United States and Canada (most common during the summer months), although no specific seasonal risk factor or factors for infection with Shiga toxin-producing *E. coli* are known. Other epidemiologic data suggest that poor children are at lower risk for the development of hemolytic-uremic syndrome, perhaps because they already have immunity to EHEC or Shiga toxins through early contact with the organisms in their environment.⁵⁰

Enteroinvasive *Escherichia coli*

EIEC is closely related to *Shigella* microbiologically and pathogenetically. The pathotype typically is found in areas with a high burden of *Shigella*. The infectious dose may be higher than that of *Shigella*, and person-to-person transmission seldom is reported. Foodborne outbreaks occur sporadically.^{94,154} The first description of EIEC as a pathotype occurred in 1971, when bloody diarrhea was traced to the consumption of French Camembert cheese contaminated with *E. coli* O124.¹⁵⁴ Small outbreaks or sporadic cases involving a limited number of serotypes have been reported from numerous countries, including the United States, France, Japan, and Brazil.^{154,190,259,282,285} The prevalence varies by region. In a rural community in Ecuador up to 20.5% of diarrheal cases were due to EIEC²³⁰; in Tunisia 11.3% of children with diarrhea had EIEC.¹⁰ Prospective studies in Thailand using DNA probes for EIEC pathogenicity genes indicated that 6% of cases of dysentery may be caused by EIEC strains.⁷⁰ Studies in Nicaragua, South India, Vietnam, Gabon, Tanzania, Denmark, and multiple sites in Africa including Kenya, Ghana, and Nigeria, demonstrated low to nondetectable rates of EIEC.^{108,169,191,192,209,216,237} The epidemiology of the cases is complicated by the fact that in contrast to the initial descriptions of EIEC-associated disease, most EIEC infections probably are neither dysenteric nor characterized by bloody diarrhea but instead manifest as watery diarrhea with low-grade fever, similar to that caused by viral agents and ETEC.

Infection with 10⁸ bacteria has been shown to be necessary for experimental dysentery in human volunteers,⁶⁹ a dose substantially higher than that for *Shigella* spp. (<10⁴ organisms). In a foodborne outbreak caused by a nontypeable EIEC, secondary person-to-person transmission was not reported.²⁵⁹

Enterotoxigenic *Escherichia coli*

EAEC was implicated first as a cause of diarrheal disease in studies of children in Chile, Mexico, and India.^{26,27,57,176} The pathogenicity of at least some EAEC strains has been established by several observations. First, volunteer studies by Nataro and associates¹⁷⁴ revealed that some EAEC could elicit diarrhea in healthy subjects, whereas other strains may not be pathogenic. Second, EAEC strains have been implicated in

outbreaks of diarrhea, the largest of which involved nearly 2700 schoolchildren in Japan.^{102,115,301} A metaanalysis performed by Huang and colleagues¹¹² of more than 20 years of studies revealed convincingly that EAEC is a cause of diarrhea in infants; adults, especially those with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) in developing countries; children in industrialized countries; and adult travelers to less-developed areas. In addition, a study from the United States by Nataro and colleagues¹⁷⁷ suggested that EAEC was the most frequent bacterial cause of diarrhea among all ages in Baltimore, Maryland, and New Haven, Connecticut.

A persisting controversy surrounding EAEC epidemiology and pathogenesis is the definition of the pathotype. The metaanalysis described earlier implicated EAEC, as defined by the characteristic stacked-brick adherence pattern to epithelial cells in culture.¹¹² A study of infant diarrhea in Cincinnati suggested, however, that only strains hybridizing with an EAEC gene probe (see later) were truly associated with clinical diarrhea.⁵² A full understanding of what constitutes a truly pathogenic EAEC strain is unavailable.

Diffusely Adherent *Escherichia coli*

The association between DAEC and diarrhea remains controversial. When DAEC was given to adult volunteers, it failed to convincingly elicit symptoms.²⁷² Additionally, this strain has been found in both healthy individuals and patients with diarrhea.^{191,246} An age-related association may exist in children older than 12 to 18 months.^{124,175,193,242,264} Of note, the commonly used *daaC* probe has been found to cross-react with some strains of EAEC, which may have led to overestimation of DAEC in some studies.²⁵⁸ Finally, DuPont and colleagues¹⁶³ suggest that DAEC may also play a role in traveler's diarrhea cases previously identified as pathogen negative.

CLINICAL MANIFESTATIONS

Diarrhea-causing *E. coli* may be responsible for a variety of clinical syndromes because virtually all known mechanisms of diarrhea, including secretory toxins, cytotoxic toxins, invasion, and pathogenic adherence, are manifested by the various *E. coli* pathotypes. The clinical manifestations are largely a function of the complement of virulence genes (see Table 104.2), and identification of the essential pathogenicity genes provides the definitive diagnostic maneuver. As with other pathogens, invasive *E. coli* strains (i.e., EIEC) produce inflammatory diarrhea with fever, abdominal pain, nausea, vomiting, and leukocytes and blood in the stool. Noninvasive, cytotoxin-producing EHEC strains cause a frankly bloody diarrhea associated with leukocytosis but without fecal leukocytes or fever. Producers of heat-labile or heat-stable enterotoxins (i.e., ETEC) elicit brisk, watery diarrhea with the potential for significant dehydration.

Enterotoxigenic *Escherichia coli*

ETEC causes watery, nonmucoid, nonbloody diarrhea in infants, older children, and adults, and it is a common cause of traveler's diarrhea.²⁰⁸ The onset of diarrhea is abrupt, with an incubation period of 14 to 50 hours.¹⁷¹ The frequency of stools varies from a few to more than 10 per day, and a striking absence of leukocytes is noted when the diarrheal stool is examined by light microscopy. Young affected children may vomit and commonly are febrile (38°C to 40°C), although adults typically are afebrile. ETEC disease cannot be distinguished clinically from most other causes of acute nonspecific watery diarrhea. The illness usually is self-limited to 3 to 5 days but occasionally lasts more than 1 week. Severely dehydrating illness that resembles clinical cholera can occur but is uncommon.

Variability in the clinical picture may be due to age differences and preexisting immunity, but it also may be attributed to differences in the infecting inoculum. DuPont and colleagues⁶⁹ produced mild diarrhea (three watery stools per day for 2 to 3 days) when 10⁸ bacteria were fed to adult volunteers, whereas 10¹¹ organisms caused more pronounced diarrhea (more than five stools per day for 4 to 5 days), with mucus but no blood observed in some subjects. Many subjects also had abdominal cramping, but no tenesmus was present, and all remained afebrile. This clinical picture is typical of traveler's diarrhea in adults.¹⁶⁵

EPEC diarrhea can result in severe dehydration necessitating aggressive fluid therapy.

Enteropathogenic *Escherichia coli*

EPEC diarrhea typically is copious and watery, without blood or fecal leukocytes.¹⁴³ Patients may have low-grade fever. In a Swiss study conducted with modern diagnostic methods, the mean age of 13 hospitalized children with EPEC diarrhea was 1.4 years (range, 0.5 to 3 years).⁷⁴ Fever was low-grade, and vomiting occurred in 69%. Volume depletion was considered moderate in five children and severe in two. Although nursery outbreaks no longer occur commonly, severe illness still can develop in infants infected with EPEC,¹¹⁹ with high mortality rates ranging from 25% to 70%.⁶³ The cause of death of patients in nursery outbreaks is not well documented. Investigations using an experimental EPEC infection model in adult volunteers (who are not naturally susceptible) revealed that watery diarrhea occurred 3 to 16 hours after inoculation and generally lasted less than 2 days. Diarrhea occasionally was copious and in some cases was associated with abdominal cramps, nausea, vomiting, malaise, and fever.⁶⁵ This clinical picture is consistent with disease caused by outbreaks of EPEC in adults.

EPEC also has been implicated in chronic diarrhea in the United States and elsewhere, with serious nutritional consequences that may require total parenteral nutrition and hospital stays of 120 days.²²⁷ In prospective studies of EPEC diarrhea in young infants in Brazil⁹³ and Ethiopia,²⁸⁰ fever, vomiting, and dehydration all were observed commonly. The clinical significance of chronic diarrhea may be increased by the underlying malnutrition of infants in resource-poor countries. In many settings, especially where effective oral rehydration programs are in place, chronic diarrhea and associated malnutrition are now more important causes of diarrheal deaths than are acute diarrhea and dehydration.³¹

In the course of the classic, severe nursery outbreaks caused by typical EPEC strains, the first signs and symptoms were mild and nonspecific, but they commonly were followed by vomiting and diarrhea of increasing severity. Stools contained neither mucus nor blood, and the volume fluctuated over a period of weeks. Plain abdominal radiographs revealed only nonspecific dilation of small bowel loops, although severe ileus not attributable to hypokalemia developed in many patients. Infected infants lost as much as 15% of body weight, leading to profound electrolyte disturbances and severe dehydration along with central nervous system manifestations, such as irritability, hypertonicity, seizures, and coma. Circulatory collapse occurred despite adequate replacement of fluids and achievement of electrolyte balance. In an epidemic in Virginia, Belnap and O'Donnell²² described fatal infections caused by *E. coli* O111:B4 occurring after 3 weeks of illness and associated with renal failure, coma, and signs of disseminated intravascular coagulation, but blood cultures typically remained negative. The fatality rate was age dependent; although the overall mortality rate was 16%, the rate in neonates was 40%. Recent epidemiologic studies suggest that typical EPEC may be common causes of diarrhea in parts of Africa with high HIV/AIDS burden.²⁰³ The etiologic link between HIV and EPEC is not clear.

The clinical description of atypical EPEC, when thought to be responsible for an outbreak, is similar to the presentation of typical EPEC.⁴ Patients present with vomiting, diarrhea, and abdominal pain. They can also present with low-grade fever. Typically, no macroscopic blood is present but the stool can be hemocult positive and fecal leukocytes have been described in a minority of patients. Atypical EPEC has also been associated with prolonged diarrhea greater than 14 days.^{4,183}

Enterohemorrhagic *Escherichia coli*

In 1971, a distinctive clinical diarrheal syndrome was recognized that was characterized by afebrile bloody diarrhea in addition to cramping and colonic inflammatory changes, usually right-sided.²¹⁷ In 1983, this illness was associated with an otherwise rare *E. coli* serotype, O157:H7, and a characteristic syndrome, hemorrhagic colitis, was defined.²¹⁸ O157:H7 subsequently was recognized as the most virulent prototype of a Shiga toxin-producing pathotype designated EHEC. EHEC now has been shown to cause a wide spectrum of diseases that may be confined to the gastrointestinal tract or, in a sizable proportion (typically

5–10%), can become systemic.^{21,276} After an incubation period of 3 to 4 days (range, 1–8 days), the local gastrointestinal illness usually begins with nonbloody diarrhea that can progress to bloody diarrhea after 1 or 2 days. Hemorrhagic colitis occurs in 50% to 90% of O157:H7 infections.^{196,276}

Further progression may occur over the course of the next day or two and result in the passage of frank blood, the pathognomonic clinical feature of hemorrhagic colitis. Associated manifestations include vomiting in approximately 50% of patients and abdominal pain. Fever may occur but typically is low grade. This clinical picture may be confused with other conditions, such as appendicitis, intussusception, inflammatory bowel disease, ischemic colitis, and diverticulitis. The difficulty in establishing the diagnosis can lead to inappropriate drug therapy or even surgery.^{96,113}

A serious complication of hemorrhagic colitis is the development of hemolytic-uremic syndrome.⁹⁶ Hemolytic-uremic syndrome is characterized by the triad of acute renal failure, thrombocytopenia, and hemolytic anemia and develops in approximately 10% to 20% of infected children younger than 10 years.¹⁷⁵ It is the most common cause of acquired renal failure in the United States.^{283,284} The acute mortality rate is approximately 55%, and renal failure is expected to develop eventually in many more patients during the next several decades. After renal failure, cerebrovascular accident and colonic perforation are the most common serious sequelae. Thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome have some overlapping clinical and pathologic features, but thrombotic thrombocytopenic purpura is increasingly regarded as a separate clinical entity that is not associated with an antecedent EHEC infection²⁷⁵; the separation is supported by its separate pathophysiology (see later discussion).

A prospective study in Canada identified *E. coli* O157:H7 in 15% of 125 patients with grossly bloody diarrhea over a 6-month period.¹⁹⁸ The age range was 15 months to 73 years; however, almost half of the patients were younger than 10 years old. The illness was similar to that described earlier, with a mean duration of 7.8 days, but it was significantly longer in children (9.1 ± 2 days) than in adults (6.6 ± 1.1 days). Sigmoidoscopy findings were abnormal in seven of eight adults examined, with hyperemic mucosa in six and superficial ulcerations in one. Biopsy samples showed mild mucosal inflammation in four of five patients. In another study, the findings on colonoscopy in 10 patients with hemorrhagic colitis caused by *E. coli* O157:H7 included severe inflammation (predominantly right sided), marked edema, easy hemorrhage, and the frequent appearance of longitudinal ulcer-like lesions.²⁵³

Because local and systemic manifestations in EHEC infection are caused, at least partially, by Shiga toxins, the presence of these same toxins in the intestinal lumen in patients with non-O157:H7 infection puts them at risk for development of hemorrhagic colitis and hemolytic uremic syndrome. Available longitudinal data suggest that O157:H7 infection results in more bloody diarrhea, hospitalization, and hemolytic-uremic syndrome than non-O157:H7 EHEC infection.^{101,105}

Enteroinvasive *Escherichia coli*

Naturally acquired EIEC infection causes a mild to moderately severe dysentery syndrome consisting of fever, malaise, diarrhea, tenesmus, and abdominal cramping.^{69,285} Watery diarrhea usually occurs at the onset of the illness and progresses to mucoid diarrhea with streaks of blood or microscopic hematochezia but rarely to the classic small-volume, grossly bloody, dysenteric stool seen with *Shigella* infection. Of 229 cases reported in one study, grossly bloody stool occurred in only four.¹⁵⁴ In two of these patients, sigmoidoscopy revealed superficial ulcerations in one and hyperemia alone in the second patient. As in *Shigella* infection, the stool reveals abundant polymorphonuclear cells, compatible with the inflammatory, invasive nature of the organism. Vomiting and dehydration can occur; the latter generally is mild. Fever of 38°C to 39.5°C (100.4°F to 103.1°F) is a typical symptom that occurs early in association with malaise, myalgia, and headache and lasts for 2 to 3 days. In most instances, the diarrhea ceases in 1 week or less, but in some patients, it may continue for 2 weeks or more.

In adult volunteers with experimentally induced EIEC disease, febrile illness developed approximately 11 hours (range 8 to 24 hours) after the inoculum was ingested.⁶⁹ Chills, myalgia, headache, and profuse

diarrhea or abdominal cramps and tenesmus rapidly followed. In two of 13 subjects, this picture was associated with systemic toxicity and transient hypotension consistent with bacteremia, even though blood cultures were negative for all patients. Clinical dysentery with bloody stools occurred in several subjects, and reddened, friable mucosa with multiple bleeding points was seen by sigmoidoscopy. Clinical illness was controlled quickly with parenteral ampicillin therapy.

Enteroaggregative *Escherichia coli*

Descriptions of EAEC clinical features are derived from outbreak investigations, volunteer studies, and studies of traveler's diarrhea.¹¹² Most EAEC infections are accompanied by watery diarrhea, which may progress to persistent diarrhea that lasts 14 days or longer.^{27,175,176} Bloody diarrhea is observed in a subset of patients.⁵⁷ An EAEC strain was implicated in a school lunch outbreak in Tajimi City, Japan, in 1993.¹¹⁵ Of 6636 children who ate the school lunch at 16 schools, 2697 (rate of attack 40.6%) reported gastrointestinal symptoms. Major symptoms were abdominal pain (73.6%), nausea (51.1%), and diarrhea (39.9%). The incubation period for the onset of gastrointestinal illness was 40 to 50 hours on average. Duration of symptoms was not reported. A nursery outbreak in Serbia involved 19 normal infants.⁵¹ All experienced watery diarrhea, which persisted beyond 2 weeks in three patients. A report of 17 pediatric patients with illness caused by EAEC of serotype O126:H27 in Israel suggested that patients typically manifested diarrhea (in all), vomiting (in eight), and fever (in 12, $\leq 40^{\circ}\text{C}$ [104°F]).²⁵¹ In this report, one 6-week-old infant developed diarrhea persisting for 40 days. Studies in travelers suggest that EAEC disease may be mildly inflammatory, although fever and fecal leukocytes are present in a few patients.¹¹² Inflammation due to EAEC may be associated with growth faltering among children in developing countries even in the absence of frank diarrhea.²⁶⁵

The particularly severe epidemic linked to an O104:H4 Stx-producing EAEC strain²¹⁴ differed from O157:H7 induced disease in several ways. Sequelae were more severe in adults than children, and overall the frequency of hemolytic-uremic syndrome and death was unusually high. Diarrhea in patients infected with O104:H4 was similar to that described in patients infected with O157:H7, suggesting that presentation of Stx at the site of infection does not require a set of virulence factors unique to EHEC strains.

Diffusely Adherent *Escherichia coli*

The association between DAEC and diarrhea remains controversial. Typically in cases in which a relationship is thought to exist, it causes a watery diarrhea that can be prolonged.¹⁷⁵

PATHOGENESIS

Enterotoxigenic *Escherichia coli*

ETEC was identified first as a porcine pathogen,^{100,256} which elicited fluid secretion when injected into ligated ileal loops.¹⁰⁰ Two secretogenic activities were characterized; one could be inactivated by heating, and the other could not, and the activities could be found both in the same strain or independently. These activities now have been assigned to two well-characterized enterotoxins, heat-stable and heat-labile enterotoxins. The heat-labile enterotoxin is genetically, structurally, and mechanistically similar to cholera toxin produced by *Vibrio cholerae* O1 strains.^{91,175} The heat-stable enterotoxin is actually two distinct toxins: STa (including closely related STI peptides STI-a and STI-b) is associated with human disease, whereas STb is associated with disease only in animals.^{82,175}

The essential pathogenic strategy for ETEC involves colonization of the proximal small intestine, followed by release of one or both of the enterotoxins. Colonization of the intestinal epithelium (Fig. 104.1) is likely initially mediated by the ETEC flagella aided by the tip adhesin, EtpA.^{228,229} The organism also secretes mucinases to facilitate access to epithelial cells.^{84,85,136,151} Colonization then becomes dependent on proteinaceous, hair-like bacterial surface appendages termed *fimbriae* (or *pili*), of which greater than 25 antigenic types are known to exist.^{170,296} As noted above, these adherence factors are termed *colonization factor antigens* or *coli surface antigens* (Fig. 104.2).⁸⁸

Human STa is a small, nonimmunogenic molecule that is translated as a 72-amino acid polypeptide.²⁶⁰ The first 19 amino acids serve as a signal sequence for secretion into the periplasmic space; a further cleavage event occurs after secretion, which results in the final 18- (ST-Ia) to 19- (ST-Ib) amino acid active peptide.^{82,175,213} The sequence of the mature heat-stable enterotoxin has six cysteine residues that form stabilizing disulfide bonds, contributing to the high stability of the toxin to heat and proteases.³⁰² The heat-stable enterotoxin receptor on the apical surface of the intestinal epithelial cells is guanylyl cyclase C. This receptor is a large transmembrane protein with an extracellular ligand-binding domain and intracellular catalytic domain; binding to guanylyl cyclase C results in its activation, which is responsible for an increase in cellular cyclic guanosine monophosphate (cGMP).²⁴⁴ cGMP is an intracellular signaling molecule that induces activation of apical chloride channels and inhibition of absorptive mechanisms, contributing to a secretory diarrhea.^{81,97,166} The heat-stable enterotoxin exploits an endogenous signaling pathway, the natural agonist of which is the peptide guanylin, a natural controller of electrolyte homeostasis.⁵⁹

The heat-labile family of toxins includes LT-I, which has significant homology in structure and function with cholera toxin, and LT-II, which

FIG. 104.1 (A) Laboratory-passaged avirulent *Escherichia coli* H10407 in infant rabbit intestine. No adherent colonizing bacteria are seen. (B) Fresh virulent H10407 organisms at the same time interval in infant rabbit intestine are closely adherent to the brush border (indirect immunofluorescent stained section, $\times 1000$). (Courtesy Drs. Dolores and Doyle Evans, Department of Microbiology, Baylor College of Medicine.)

FIG. 104.2 (A) Electron micrograph of negatively stained cells of avirulent plasmid-cured *Escherichia coli* H10407. Note the bald appearance of the outer surface of the organism. (B) Similar view of virulent fresh *E. coli* H10407. Note the hairy surface of the organism as a result of colonization factor antigen I ($\times 20,000$). (Courtesy Drs. Dolores and Doyle Evans, Department of Microbiology, Baylor College of Medicine.)

does not seem to cause human or animal disease.¹⁷⁵ LT-I shares 80% identity with cholera toxin and similarly has an A₁-B₅ stoichiometry.^{90,164,175,255,268} The 28-kd A subunit is the catalytically active moiety, whereas the 11-kd B subunit pentamer mediates cell binding and entry. Heat-labile enterotoxin interacts with G_{M1} gangliosides on the surface of the epithelial cells.^{82,141,175} The A subunit is composed of two domains, termed A1 and A2, which are bound via a disulfide bond. A1 has adenosine diphosphate-ribosyl transferase activity, which targets the cellular guanosine triphosphate binding protein G_{sα}, a regulator of cellular cyclic adenosine monophosphate (cAMP) levels. Ribosylation of G_{sα} leads to constitutive activation of adenylate cyclase, which greatly increases cAMP levels.^{82,245} Increased cAMP leads to increased phosphorylation of chloride channels, especially the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR), by protein kinase A, and increased chloride secretion, which also may contribute to secretory diarrhea.^{82,245} The heat-labile enterotoxin additionally seems to promote *E. coli* adherence to epithelial cells, a function which is dependent on ADP-ribosylation, although the mechanism remains unclear.¹²¹

Enteropathogenic *Escherichia coli*

EPEC pathogenesis is complex and only partly understood. In contrast to ETEC, it possesses no potent secretogenic toxin but rather induces changes to the enterocyte signal transduction environment, which transforms the enterocyte from an absorptive cell to a secretory cell. EPEC pathogenesis has been described as a multistep process. The first step comprises attachment to the small bowel mucosa, an event mediated by the EPEC adherence factor plasmid-encoded, bundle-forming pilus. The bundle-forming pilus is a complex surface fimbrial structure, expressed by classical or typical EPEC, that may undergo contraction, not only tethering the bacteria to the cell but also pulling itself close to the cell's apical membrane.¹³³ Atypical EPEC are missing the bundle-forming pilus and must rely on other adhesion factors.¹⁸⁹ Approach of the bacteria is followed by induction of a characteristic lesion, termed *attaching and effacing*. Under electron microscopy, the normal microvillus architecture is dissolved, and the bacterium adheres tightly (<20 nm distance) to the now protruding cell membrane (Fig. 104.3). This deceptively simple phenotype is mediated and accompanied by a dizzying array of invisible changes to the cell's internal environment.⁶³

Cellular changes are induced largely by a platoon of protein toxins that the bacterium injects directly into the cytoplasm of the target host cell. This injection process is mediated by a complex bacterial organelle

FIG. 104.3 High-power electron micrograph of intestinal epithelium infected by typical enteropathogenic *Escherichia coli* strains (*E*), with occasional intact microvilli (*MV*) and pedestal formation (*double arrows*). This figure shows not only the structural alterations and loss of the brush border but also the close apposition of the organisms to the epithelial cells. (Courtesy Ralph A. Gianella, Department of Medicine, University of Cincinnati School of Medicine.)

termed an *injectisome*, also known as a *type III secretion system*. The first toxin injected is referred to as the *translocated intimin receptor* (Tir). Tir inserts itself into the apical plasma membrane, where it serves as the receptor for the bacterial outer membrane adhesion protein, *intimin*. As its name suggests, intimin mediates very close attachment of the bacterium to the cell and contributes to the resulting cytoskeletal damage.⁴⁶

The net effect of Tir, intimin, and other injected toxins is dissolution of the microfilament and microtubule networks, phosphorylation of membrane ion transporters, and disruption of tight junctions at the cell's periphery.^{137,179,299} Diarrhea apparently is caused by a combination of ion transport and paracellular leakage.²⁹³ Release of proinflammatory cytokines may complete the pathogenic cascade. The relative contributions of each of these events to EPEC disease are unknown.⁴⁶

EPEC adhere to HEp-2 epithelial cells in a characteristic localized pattern, which has been suggested as a diagnostic assay (Fig. 104.4).⁶³

FIG. 104.4 Patterns of adherence of *Escherichia coli* to HEp-2 cells in tissue culture. Typical enteropathogenic *E. coli* associates with HEp-2 cells in the pattern shown in (A) termed localized adherence (LA). Arrows point to cells where growing microcolonies of bacteria are attached to focal areas of the cell membrane. Other *E. coli* organisms isolated from patients with diarrhea adhere over the entire HEp-2 cell membrane, as shown in the cells identified with arrows in (B). This pattern of interaction is termed diffuse adherence (DA). Although the LA phenotype has been associated definitively with the capacity to induce diarrhea in experimental models, evidence of virulence in DA strains remains controversial.

FIG. 104.5 Some *Escherichia coli* strains have the capacity to attach to the eukaryotic cell membrane and induce polymerization of actin beneath the membrane. This property may be shown by the fluorescent actin staining test, in which polymerized F-actin is detected by a fluorescein-tagged mushroom toxin specific for this form of actin. In this figure, the bacteria are attached to HEp-2 cells, and the induced actin polymerization revealed by the fluorescent reagent highlights the organisms, which are seen as bright rods on the infected cells.

Also, EPEC causes actin polymerization of target cells at sites of attachment, a virulence property readily detected in tissue culture (e.g., HEp-2 cells) by a fluorescent actin-staining test (Fig. 104.5).¹³² As discussed subsequently, these phenotypic assays, although useful for pathogenesis studies, have largely been replaced by molecular diagnostic tests.

Enterohemorrhagic *Escherichia coli*

The cardinal pathogenic feature of the EHEC pathotype is the production of Shiga toxin, accompanied by a cohort of accessory virulence factors. As with EPEC, these factors are encoded by the bacterial chromosome

and a high-molecular-weight virulence plasmid. Shiga toxin is encoded on a lysogenic phage, which is capable of infecting some non-EHEC *E. coli* strains. The full package of virulence genes has been well characterized in serotype O157:H7; studies which characterize locally obtained EHEC strains suggest that non-O157 pathogens are a heterogeneous group and tend to share some, but not all, of the virulence traits, accounting for their reduced virulence and frequency.^{19,125,153} Shiga toxins were discovered by Konowalchuk and associates,¹³⁴ who reported finding Vero cell toxic activity in culture filtrates of certain strains of *E. coli* isolated from patients with diarrhea (Shiga toxin occasionally has been referred to by the archaic synonym *Vero toxin*).

Shiga toxins constitute a family of protein toxins that share identical enzymatic action and target cell binding specificity. Shiga toxins are subdivided into two families, Stx1 and Stx2, each consisting of the major Stx type and variants (i.e., Stx1c, Stx1d, Stx2c, Stx2c2, Stx2d_{EH250}, Stx2d_{activatable}, Stx2e, and Stx2f).²⁹ Stx2 and Stx2c have been associated with severe disease, including hemorrhagic colitis and hemolytic-uremic syndrome.^{87,197} Stx2d_{activatable} can be activated by mouse and human intestinal mucus and is associated with a severe clinical phenotype.²⁹ The greater pathogenicity of Stx2 may be due to greater accessibility of the active site on the Stx2 structure.⁸⁵ The *stx1* gene differs from the *Shigella stx* gene by three nucleotide changes, which result in a single conservative amino acid substitution in the A subunit: threonine to serine.¹⁰⁹

Shiga toxins have the same structure and mechanism of action. They have an A₁-B₅ stoichiometry, comprising a single enzymatically active A subunit and a pentamer of B subunits responsible for toxin binding. The B subunits bind to globotriaosyl ceramide (Gb₃) and related glycolipids on host cells, including epithelial enterocytes, vascular endothelial cells, smooth muscle cells, renal endothelial cells, and erythrocytes.^{66,139} The catalytic A subunit cleaves the N-glycosidic bond in a specific adenosine of the 28S rRNA in the 60S ribosomal subunit.⁷¹ This single cleavage event results in irreversible cessation of protein synthesis and ultimately leads to cell death via multiple signal transduction pathways.⁵³ Intestinal villus cells are susceptible to the action of Shiga toxin, which includes reduced absorption of sodium. Data suggest that Shiga toxin

induces local inflammatory cytokine production, with potential effects on epithelial cell and mucosal integrity. This host response may induce a vicious cycle because both hydrogen peroxide and neutrophils augment production of Shiga toxin.²⁹²

Epidemiologic evidence strongly links Shiga toxin-producing strains to hemorrhagic colitis and to the associated systemic complications of hemolytic-uremic syndrome.^{95,127,218} The mechanisms underlying hemolytic-uremic syndrome are becoming clearer. Shiga toxin-induced disease appears to be due to the effects of toxin on vascular endothelial cells, possibly in concert with bacterial lipopolysaccharide. These activate secretion of a variety of cytokines, which initiate events resulting in endothelial cell injury and platelet thrombi, and subsequently, the characteristic thrombotic microangiopathy.^{50,128,187} Shiga toxin activates complement and binds Factor H, a complement regulator, leading to excess complement activation and deposition.^{54,194} Other possible pathophysiologic derangements include abnormal levels of von Willebrand factor, but whether this abnormality is a cause or a consequence of disease is unknown.¹⁶⁷ Stx1 has been shown to decrease production of prostacyclins; however, the role of this event in the pathogenesis of hemolytic-uremic syndrome is uncertain.¹²⁸ Of note, thrombotic thrombocytopenic purpura results from autoantibodies against or mutations in the von Willebrand factor metalloprotease ADAMTS13.²⁷⁵

Similar to EPEC, EHEC express the intimin outer membrane protein and a type III secretion apparatus.¹⁷⁵ EHEC are capable of inducing complex cytoskeletal alterations similar to those caused by EPEC infection, although certain subtle differences are observed. EHEC infects the human colon, whereas EPEC is an infection of the small bowel. The genes encoding intimin, Tir, the type III secretion system, and secreted proteins reside on a 35-kb pathogenicity island called the locus of enterocyte effacement, which may be more crucial for EPEC than for EHEC for virulence.⁶⁶ A 60-Md plasmid, pO157, which contains genes encoding an enterohemolysin, is commonly found in O157:H7 strains, but its role in production of disease is unclear.¹⁷⁵ Subtilase cytotoxin (SubAB), a novel cytotoxin with an A₁-B₅ stoichiometry, is associated with hemolytic-uremic syndrome in diverse EHEC strains in Australia and the United States.^{130,202} SubAB is heat-stable, more toxic to Vero cells than Shiga toxin, and lethal when injected in mice.^{130,202} Cytotoxicity is the result of direct cleavage of an endoplasmic reticulum chaperone protein, BiP.²⁰¹

Enteroinvasive *Escherichia coli*

In 1967, Trabulsi and coworkers²⁸² in Brazil and Sakazaki and associates²³⁵ in Japan described the isolation of certain *E. coli* serotypes from patients with a disease resembling bacillary dysentery, but with cultures negative for *Shigella*. These isolates possessed a critical virulence hallmark associated with *Shigella*—the ability to invade intestinal and other epithelial cells (Fig. 104.6).¹⁸⁷ They have been referred to as EIEC, and a limited number of serotypes, distinct from the EPEC O groups, but often cross-reactive with *Shigella* O antigens, have been found to possess this property (see Table 104.1). The genetic and molecular basis of invasion by *Shigella* was well defined in the 1990s, and the same plasmid and chromosomal genes encoding invasion properties and mechanisms seem to be present in EIEC as well.^{111,144,200,238}

The invasive process for EIEC is thought to be the same as that for *Shigella* spp. It involves four main steps: (1) initial entry into cells, (2) intracellular multiplication, (3) intracellular and intercellular spread, and (4) host-cell killing. The process is complex and involves multiple genes on the invasion plasmid and the chromosome.^{1,12,287} Intracellular *Shigella* and likely EIEC are able to escape autophagy/xenophagy.¹² They additionally take advantage of the immune response to promote an invasive phenotype.²⁸⁷ EIEC produces toxins reported to be structurally distinct from the Stx of *Shigella dysenteriae* type 1 and the Shiga toxins 1 and 2 of EHEC.⁷⁸ Nonetheless, studies suggest that EIEC toxins possess many properties in common with the Shiga toxin family of toxins, including the ability to cause fluid secretion in animal models.⁷⁸ EIEC may contain a plasmid-borne gene that encodes a 63-kd protein called *ShET2* (*Shigella* enterotoxin 2); a mutation in this gene substantially decreases the enterotoxigenic activity of the parent strain.¹⁷⁸ The virulence of EIEC is notably less severe than *Shigella*. Several groups have noted that the expression of virulence genes by EIEC using in vitro models

FIG. 104.6 Electron micrograph of enteroinvasive *Escherichia coli* infection of intestinal mucosa. The intracellular location of the bacteria clearly is seen within membrane-bound vesicles in two adjacent infected cells. The pathogenesis of enteroinvasive *E. coli* infection involves the invasion of intestinal cells and local cell-to-cell spread, as shown here, by a mechanism identical to that of *Shigella* spp. (Courtesy Saul Tzipori, DVM, Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)

of infection is diminished as compared to *Shigella*.^{261,263} However, the differences leading to less severe disease in vivo are still not clear.

Enteraggative *Escherichia coli*

The pathogenesis of EAEC includes adherence to the intestinal epithelium as a thick biofilm, accompanied by mucus hypersecretion, intestinal damage, and induction of an inflammatory response. Most of these phenotypes seem to be mediated by a set of bacterial cytotoxins and enterotoxins.¹⁰³

Adherence and colonization of the intestinal epithelium are mediated by pili called *aggregative adherence fimbriae*, of which several allelic variants exist. EAEC may colonize the large and small intestines.¹⁰⁷ All known aggregative adherence fimbriae variants are encoded on high-molecular-weight virulence plasmids collectively termed *pAA*. Also encoded on *pAA* is a transcriptional activator of the fimbrial genes, *AggR*. *AggR* is emerging as a global regulator of virulence functions in EAEC⁶⁷; also under *AggR* control is a gene encoding a surface protein nicknamed *dispersin*. In the absence of *dispersin*, the aggregative adherence fimbriae adhesins collapse onto the surface of the bacterium.³⁰⁵ Several cryptic genes, including a large chromosomal locus, also are under *AggR* control. One recently discovered gene product, termed *Aar*, acts to check *AggR*-mediated activation, resulting in finely tuned gene regulation.²³⁹

Damage to the intestinal mucosa has been linked to the presence of a secreted enterotoxin named plasmid-encoded toxin (*Pet*).⁷³ *Pet* is a protease that is internalized by target epithelial cells, where it cleaves cytoskeletal proteins, including spectrin. The net effect of these cleavage events is induction of fluid, secretion of electrolytes, and, ultimately, exfoliation of cells from the mucosal surface.¹⁰⁶

EAEC strains also harbor a homologue of the ETEC heat-stable toxin, enteraggative heat-stable enterotoxin,²⁴¹ and a chromosomally encoded toxin called *Shigella* enterotoxin 1.⁷⁹ Inflammation by EAEC has been linked to the expression of the bacterial flagellum, although studies in polarized epithelial monolayers suggest that additional factors under control of *AggR* also are required.¹⁰³

Diffusely Adherent *Escherichia coli*

As their name implies, DAEC are categorized by their adherence pattern on Hep-2 cells. Their pathogenesis is not well delineated. They characteristically contain nonfimbrial adhesins referred to as Afa/Dr adhesins (Afa/Dr DAEC). Along with a fimbrial adhesin, F1845 found in prototypical strain C1845 and a majority of DAEC strains, these adhesins bind to human decay-accelerating factor and, depending on the subtype of DAEC, carcinoembryonic antigen related molecules.^{124,140,246} Binding then leads to invasion by a zipper-like mechanism¹²³ and a resulting inflammatory response.^{17,23,24,40,246} Few virulence factors have been elucidated for DAEC. However, Sat, a member of the autotransporter family of toxins, has been found in DAEC strains thought to be diarrheagenic, causes lesions, triggers autophagy in vitro in epithelial cells, and causes intestinal damage in an animal model.^{99,145,274}

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diarrheogenic *E. coli* can be identified best by detecting their defining virulence genes. Many molecular tests are described for this purpose. The FDA has recently approved multiplex platforms for use in the diagnosis of enteric pathogens, including PCR-based techniques to identify multiple *E. coli* pathotypes (EPEC, ETEC, STEC, EIEC, EAEC) from patient samples.^{36,304} However, these are not yet widely utilized. For most pathotypes, consultation with an expert, such as the senior author or the *E. coli* reference laboratories at the CDC, is recommended. Detection of *E. coli* generally is indicated for severe and persistent diarrhea lacking any other diagnosis (particularly in returning travelers) or in the setting of diarrheal outbreaks of unknown cause. With the exception of EHEC, most infections caused by diarrheogenic pathotypes are self-limiting.

Because of the potential of EHEC to cause serious sequelae, establishing a specific diagnosis is of clinical and epidemiologic importance. The earlier in the course of illness that a stool specimen is obtained, the more likely that *E. coli* O157:H7 will be recovered²⁷⁷; recovery more than 7 days after onset of diarrhea is unusual. The laboratory can use sorbitol-MacConkey agar to screen colonies for lack of sorbitol fermentation or substrates such as 4-methylumbelliferyl- β -D-glucuronide (MUG) for the production of γ -glucuronidase; *E. coli* O157:H7 is almost uniquely sorbitol negative and glucuronidase negative. These techniques have limited sensitivity, with the sensitivity of sorbitol-MacConkey agar reported as 50% to 60%.¹²⁹ Some sorbitol-fermenting O157:H7 isolates and many other sorbitol-fermenting, non-O157 EHEC capable of causing severe illness and hemolytic-uremic syndrome would be missed by sorbitol-MacConkey agar.

Detecting Shiga toxin in stool specimens, either directly or after overnight broth enrichment, currently is the most sensitive method for identifying EHEC after the first 7 days of illness.¹²⁹ These tests, immunoassays and PCR assays that identify shiga toxin 1 or 2 or *stx* genes, are more sensitive than culture techniques and are not dependent on serotype.^{25,80,173} Despite the detection of Shiga toxin by these rapid assays, isolation of the organism, usually performed at reference laboratories, remains crucial for serotyping and other epidemiologic purposes. Serotype-specific commercial antigen immunoassays also are available.¹⁷³

Diagnosis of ETEC traditionally would require identifying the heat-labile enterotoxin or heat-stable enterotoxin genes in an isolate or, after isolation and growth in vitro, by DNA probes or by detecting their products using enzyme-linked immunosorbent assay (ELISA). Multiplex PCR assays for detection of toxins and colonization factor antigens have been developed and are rapid, sensitive, and used with increasing frequency.^{61,223} PCR techniques are additionally available that allow virulence factors to be detected directly from stool or environmental sources without the need for performing culture.^{37,149} A retrospective diagnosis can be made by detecting an increase in antitoxin antibody, especially for the heat-labile enterotoxin. ELISA for colonization factor antigens of ETEC also could be useful.

EPEC can be detected reliably by DNA probes for the 60-Md EPEC adherence factor plasmid or by adherence to cells in culture. The ability of *E. coli* to adhere to HEp-2 cells in culture in distinct morphologies led to the description of EPEC, EAEC, and DAEC as different pathotypes

FIG. 104.7 Enteroaggregative *Escherichia coli* (EAEC) infection of the gnotobiotic pig intestine. This photomicrograph shows the characteristic “stacked brick” appearance of the aggregative organisms over the surface of the intestinal epithelium in vivo in the same manner described for EAEC adherence to HEp-2 cells in tissue culture. (Courtesy Saul Tzipori, DVM, Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)

(see Fig. 104.3). After a 3-hour incubation of bacteria with cells, EPEC adheres to the cell in tight microcolonies, called the *localized adherence* pattern. Although it remains sensitive and specific for EPEC, this method has been replaced by molecular detection methods to detect the locus of enterocyte effacement island (via the intimin-encoding gene *eae*) and the EPEC adherence factor plasmid (often via detection of the BFP-encoding genes).⁶⁴

EAEC can be detected by the presence of the aggregative adherence pattern in the Hep-2 adherence assay (Fig. 104.7). DNA probes and PCR are available to detect the AggR regulon, and these tests are likely to provide more specific detection of EAEC pathogens.⁵²

EIEC is detected best using molecular techniques that are specific for detection of pathogenesis-related genes. Several multiplex PCR assays that allow the user to screen for multiple *E. coli* pathotypes simultaneously have been described.^{16,146,205} Additionally, it is possible to differentiate between *Shigella* spp. and EIEC using these techniques,²⁰⁴ which can be introduced readily into any molecular biology laboratory and produce excellent results.

DAEC can be detected by a diffuse adherence pattern on Hep-2 cells.^{191,246} A probe, commonly used in epidemiologic studies, which targets *daaC*, part of the F1845 operon, has recently been shown to cross-react with some strains of EAEC.^{246,258} PCR methods are available for detection from stool.^{163,246}

PROGNOSIS

EPEC, EAEC, and ETEC do not cause systemic infections or complications except those resulting from dehydration or the consequences of nutritional depletion. The prognosis is related directly to the availability and adequacy of fluid therapy. When this need is dealt with correctly in an otherwise healthy and well-nourished patient, the principal complication is the rare instance of monosaccharide intolerance. In infants or young children in developing countries with protein-energy malnutrition, however, chronic diarrhea and progressive worsening of nutritional status frequently are observed, sometimes resulting in mortality. When food is withheld from either well-nourished or poorly nourished children, hypoglycemia may occur and produce seizures, coma, or death. Rarely, loss of water in excess of salt causes hypertonic dehydration, with serum sodium concentrations greater than 160 mEq/L, a situation that may cause seizures, coma, and death.

As noted earlier, EAEC has been associated with persistent diarrhea lasting longer than 14 days in young infants and children. Persistent diarrhea leads to nutritional deterioration, may be difficult to control,

and may culminate in death from sepsis or other infections. Inflammatory diarrhea caused by EIEC also results in nutritional deterioration, with significant protein losses occurring via the gut.

EHEC infections can be followed by hemolytic-uremic syndrome, neurologic, and intestinal complications. Ten percent of patients may die early in the course of the systemic phase of hemolytic-uremic syndrome. Although the renal failure of hemolytic-uremic syndrome may be reversible with good management of fluid and electrolytes and the use of dialysis as needed, permanent damage to the kidneys is, contrary to earlier more optimistic assessments, likely to occur in 25% or more of patients over the course of 1 or 2 decades, and many of them require permanent dialysis or transplantation in the future.⁸⁹ Symptoms of chronic renal disease may appear more than one year after the initial presentation of hemolytic-uremic syndrome, suggesting that follow-up of these patients should be continued for at least 5 years, even for patients who appear to be recovered.²²⁵

TREATMENT

In all age groups, the principal treatment of the intestinal manifestations of *E. coli* enteric infection is replacement of fluids and electrolytes; with maintenance of fluid balance, the disease is self-limited to 1 week or less in most patients and lasts no more than 2 weeks in nearly all patients. The earlier that fluid replacement therapy is begun, the better the prognosis, particularly considering that clinical signs of dehydration do not develop until a 5% loss of body weight occurs, and that sustained loss of more than 10% of body weight is incompatible with survival.

When shock is present (usually with altered consciousness and an absent or thready pulse) or oral rehydration is unsuccessful because of persistent vomiting, patients must be rehydrated by intravenous infusion of an isotonic electrolyte solution, such as lactated Ringer solution or normal saline. Alternatively, several prerequisites must be ensured for oral therapy: (1) the patient must not be in shock; (2) the patient must be fully conscious; (3) the patient must be able to drink (vomiting, particularly common in children, is not an absolute contraindication because frequent small oral feedings usually are largely retained; when the metabolic abnormality begins to reverse toward normal, vomiting ceases); (4) bowel sounds must be present; and (5) renal function must be normal. Current recommendations for oral rehydration in the United States and Europe suggest the use of hypotonic fluid containing 60 to 75 mEq of sodium per liter (along with potassium and carbohydrates). In the developing world, where cholera is a common occurrence, the World Health Organization recommends that a solution containing 75 mEq of sodium be used for all cases of diarrhea.^{9,294} Monitoring for electrolyte imbalances may be required. Rice-based solutions for oral rehydration currently are favored in many diarrheal centers because of their reduced osmotic load.¹³¹ Additionally, zinc supplementation may be of benefit in reducing the duration of acute diarrhea and preventing further episodes.^{28,131,267}

A prospective cohort study comparing *E. coli* O157:H7 hemolytic-uremic syndrome patients who developed oligoanuric renal failure requiring dialysis with patients with nonoligoanuric renal failure found that the patients who required dialysis had received less intravascular volume expansion and sodium than the patients who did not require dialysis, suggesting that intravascular volume expansion with isotonic fluid was protective for oligoanuric renal failure when given early in the course of O157 infection.⁸ The authors advocate hospitalizing all children with suspected EHEC infection for volume expansion with isotonic fluids and close monitoring.

Although rehydration therapy is the cornerstone of management, antibiotic therapy should be considered in some cases. In most *E. coli*-associated diarrheal illnesses, the disease is mild and of short duration, and no specific antimicrobial therapy is required. Studies to address this issue have found antibiotics to be beneficial in some circumstances. In traveler's diarrhea secondary to ETEC, antibiotic therapy can shorten the duration of illness and decrease its severity.^{14,72} Prophylactic antibiotic therapy probably carries more risk than benefit, however, and generally is not recommended unless a significant reason exists for the traveler to require prophylaxis. Because of increasing rates of resistance to trimethoprim-sulfamethoxazole (TMP-SMX), it is no

longer recommended for treatment or prophylaxis.⁶⁸ For moderate to severe traveler's diarrhea (both ETEC and EAEC), rifaximin, ciprofloxacin, and azithromycin for 1 to 3 days have been shown to have some efficacy. Rifaximin is not absorbed from the gastrointestinal tract which provides a more favorable side effect profile. However, if symptoms occur, such as high fever (39.4°C [102.9°F]) or grossly bloody stools, suggesting a more invasive pathogen, azithromycin is recommended instead (10 mg/kg per day for 3 days in children >6 months).^{61,68} Fluoroquinolones (ciprofloxacin) are considered to have a potential undesirable side effect profile in children although 1 to 3 days as recommended for traveler's diarrhea would likely be safe. Of note, resistance to fluoroquinolones does continue to increase which warrants continued monitoring and judicious use.¹⁶² Children in developing countries with ETEC diarrhea also may benefit from receiving antibiotic therapy.^{168,186}

EIEC infection theoretically would benefit even more from antibiotic therapy, given its pathogenic similarity to shigellosis and the known benefits of the early use of antibiotics. No controlled studies have validated this benefit for EIEC, however. In experimentally induced disease, DuPont and colleagues⁶⁹ reported that parenteral ampicillin produced a bacteriologic cure and rapid clinical response with defervescence and improvement of diarrhea in adults. They have also used ampicillin in the pediatric population for severe dysentery caused by EIEC.²⁶² TMP-SMX and ampicillin are the current drugs of choice, although resistance has been reported.⁶

Immunocompromised hosts, especially children with AIDS, may require prolonged antibiotic therapy for protracted or recrudescing diarrhea, even when it is caused by bacteria that normally produce only self-limited disease. Malnourished children and children with other serious underlying illness also fit this category. In these patients, systemic invasion may develop along with associated complications, including shock and renal failure. In addition, prolonged carrier states are common findings, with frequent relapses requiring long-term antibiotic therapy for suppression of relapse.

Epidemic EPEC infection, especially in newborns, seems to be affected favorably by antibiotic therapy.¹⁸⁰ The potential for this pathogen to cause prolonged disease and a history of high rates of mortality in neonates suggest the need for antibiotic trials in this age group. Based on limited data, either TMP-SMX or oral nonabsorbable antibiotics, such as gentamicin or colistin, usually are recommended, although antibiotic resistance is common and may alter the choice of antibiotics based on local susceptibility patterns.^{18,289}

Antibiotic treatment of EHEC is not recommended. Antibiotics in clinical use do not improve the course or prevent sequelae, and they may exacerbate the illness by promoting production and release of Shiga toxin.^{11,30,48} In vitro data suggest that subinhibitory concentrations of TMP-SMX and other antibiotics may increase expression of Shiga toxin.^{18,126,156} The most rigorous prospective study to address this question found that the cohort who received antibiotics had a higher incidence of hemolytic-uremic syndrome (of 25 patients who received antibiotics, nine developed hemolytic-uremic syndrome) than the cohort who did not (of 234 patients who did not receive antibiotics, 27 developed hemolytic-uremic syndrome; $P < .001$).^{297,298} Other studies have found no association.^{196,234}

Notably, no studies have used a randomized placebo-controlled design, so the association may reflect selection bias because both the use of antibiotics and systemic complications are associated with more severe disease. A metaanalysis²³⁴ did not show a higher risk of hemolytic-uremic syndrome associated with antibiotics; however, this metaanalysis has been criticized because it included a study in which all of the patients received antibiotics¹¹⁴ and because comparisons were made among different antibiotics, which may not induce similar sequelae.

Ecuzumab, a monoclonal C5 antibody that targets terminal complement complex formation, has been shown in a small case series ($n = 3$) to be effective in improving refractory severe hemolytic-uremic syndrome.¹³⁸ Further follow-up of hundreds of patients in Germany who had Shiga toxin-positive EAEC during a 2011 continental outbreak suggests possible benefit.^{62,195}

Antimotility agents such as loperamide generally are not needed and should be used cautiously if prescribed, with great attention paid to dosage, especially in very young patients.²⁷⁹ Dysentery is a

contraindication to the use of antimotility agents, which may be a risk factor for the development of ileus and abdominal distention.³ The prolonged use of antimotility agents is reported to be associated with more serious systemic complications of EHEC infection and is not recommended.^{48,49}

In most instances of *E. coli* diarrhea, the clinician is left to make therapeutic decisions without knowing the etiologic agent responsible. For reasons already outlined, routine diagnostic microbiology laboratories cannot distinguish pathogenic from nonpathogenic *E. coli*, with the exception of classic EPEC serotypes and Shiga toxin-producing *E. coli* including O157:H7 EHEC. Clinical decisions regarding the administration of antibiotic therapy are made on purely clinical grounds with criteria such as the history, duration, and severity of the illness; the age and immunologic competence of the patient; and the nature of the diarrheal stool (e.g., watery, inflammatory, bloody, or dysenteric). Empiric antimicrobial therapy is more justifiable for immunocompromised hosts, for patients with prolonged or severe illness or a history of relevant risk factors (e.g., specific food ingestion, travel, exposure to known contacts), and for cases of inflammatory or dysenteric illness.

Research on alternative treatments of EHEC and prevention of hemolytic-uremic syndrome is ongoing. A synthetic verotoxin receptor, SYNORB Pk, was not shown to prevent death, dialysis, or serious extrarenal events in a trial of 145 children with EHEC-induced hemolytic-uremic syndrome.²⁸⁶ Although antibodies against *E. coli* O157 intimin were protective for colonization and disease in a pig model,⁶⁰ plasmapheresis and intravenous immunoglobulin have not been shown to ameliorate hemolytic-uremic syndrome in humans.^{222,290} Investigation of monoclonal antibodies directed against Shiga toxin are under way.^{161,286} The complete genome sequence of *E. coli* O157:H7 is now known and may lead to greater understanding of the pathogenesis of hemorrhagic colitis and hemolytic-uremic syndrome and perhaps innovative approaches to treatment and prevention.¹⁰⁴

PREVENTION

Epidemic nursery outbreaks of diarrhea in newborns can be controlled by the application of classical principles of preventive medicine. Prompt diagnosis and treatment and scrupulous attention given to details of hand washing and environmental sanitation to eliminate person-to-person transmission are still effective, whereas prophylactic antimicrobials have no role. Outbreaks in neonatal nurseries can be contained by epidemiologic control measures such as cohorting; by screening staff for carriage; and, if necessary, by closing the unit until it is decontaminated. In contrast, preventing sporadic cases of *E. coli* diarrhea is difficult. In communities with obvious deficits in water supply and feces disposal, correction of these problems would lead to a diminished incidence of diarrheal diseases in general.

For traveler's diarrhea, avoidance of contaminated sources such as tap water, unpeeled fresh fruits, and large quantities of ice can be effective in prevention. Several studies additionally indicate that prophylactic antibiotics can protect adult travelers, at least for a limited time.⁹⁸ The risk of selection of resistant organisms and drug side effects limits the use of antibiotic prophylaxis to short-term travelers with business or diplomatic missions that would be hindered significantly by an episode of diarrhea. Fluoroquinolones, azithromycin, and rifaximin have been evaluated for prophylaxis and presumptive treatment, and all are efficacious.²⁵⁴ Some evidence has been presented for the moderate efficacy of bismuth compounds, such as bismuth subsalicylate, for the prevention of ETEC diarrhea in adults. The concern for bismuth toxicity with prolonged use in young children would render it a problematic solution for pediatric *E. coli* diarrhea and its prevention.^{68,215}

ETEC vaccine development has been propelled by the observation that ETEC infection confers some protection from reinfection with the same strain,²⁶⁶ also evident in the decreasing rates of infection in children older than 5 years.²⁰⁸ The challenge is that more than 25 colonization factor antigens have been identified, and strain serotypes vary tremendously across the world.⁹² As noted previously, however, it also is known that certain serotypes and colonization factor antigens are most common (i.e., colonization factor antigens I, II, and IV) and tend to co-segregate with certain virulence factor combinations.^{88,92,291,296} This factor would

limit the antigenic variability needed in an effective vaccine. Many isolates of ETEC expressing only the heat-labile enterotoxin do not express known colonization factors and would be unaffected by a colonization factor antigen-based vaccine. Although no ETEC vaccine currently is licensed and available, several approaches have been attempted. Dukoral, a vaccine licensed in Europe and Canada for prevention of cholera, has been demonstrated to have some short-term efficacy against ETEC-associated traveler's diarrhea and may be useful to for travelers to high-risk areas.¹¹⁸ Among the ETEC vaccines furthest in development is one that began as a combination of recombinant cholera toxin B (as a surrogate for the LT toxin subunit) with strains of formalin-killed ETEC expressing the most prevalent colonization factor antigens in developing countries (rCTB-CF ETEC).²⁶⁹ This vaccine was found to prevent 77% of nonmild ETEC diarrhea in travelers to developing countries.^{208,233,269} In a study of Egyptian children, however, it was not efficacious in preventing disease.^{32,208} Reformulation of this vaccine (ETVAX) now includes increased content of CF antigen as well as a new adjuvant (dmlT, an attenuated form of LT) and has shown promise in clinical trials.^{34,110,150,269}

Other avenues of vaccine development that have been pursued include live, attenuated ETEC vaccines^{34,158} and subunit vaccines. The heat-stable enterotoxin does not create a significant immune response; however, the heat-labile enterotoxin is a known adjuvant similar to cholera toxin and has been conjugated to the heat-stable enterotoxin.^{32,92,147,303} Concerns for human use of this construct come, however, from the homology of heat-stable enterotoxin to guanylin, which is produced endogenously.^{32,59,278} Live, attenuated *Shigella* vaccine vectors also are being studied in an attempt to elicit a mucosal immune response. Researchers have studied new methods of delivering antigens to the mucosa, including encapsulation in microspheres, delivery in recombinant foods,^{271,270,273} and a transcutaneous heat-labile enterotoxin patch vaccine, which was shown to elicit an antibody response but not protect against symptomatic infection.^{20,86,157} Finally, new vaccine candidates are being identified, such as novel virulence factors including the EtpA adhesin, EatA and YghJ, secreted metalloproteases, and EaeH, an ETEC surface protein. Many of these virulence factors are conserved in a majority of ETEC strains.^{34,84,136,228,229,252} Although no vaccine is yet licensed in the United States, work continues to advance in this field in an attempt to decrease the incidence and severity of morbidity from dysentery in the developing world and from traveler's diarrhea.

Vaccine development for other diarrheogenic *E. coli* strains lags behind that for ETEC. Because EHEC-induced hemolytic-uremic syndrome is a rare disease, vaccine development for humans is limited. However, one group is pursuing vaccination as part of the primary infant series because young age is a risk factor for the development of hemolytic-uremic syndrome. An O157:H7 O-specific polysaccharide conjugated to recombinant exotoxin A of *Pseudomonas aeruginosa* (O157-rEPA) vaccine was shown to be safe and immunogenic in children in a phase 2 study.^{7,160} Vaccine development for cattle, the major reservoir, is ongoing²⁵⁷ and has now yielded two available cattle vaccines.¹⁶⁰ A vaccine composed of type III secreted proteins resulted in decreased shedding of *E. coli* O157:H7 in contrast to controls, although prevalence of shedding increased over the study period. Repeat vaccination of cattle may serve as a mode to decrease human exposure to EHEC.²⁰⁶

Klebsiella

Debra J. Lugo • Randall G. Fisher

Klebsiella is a genus of Enterobacteriaceae, a frequent cause of nosocomial pediatric infection. Classically described by Friedländer⁴⁸ as a cause of pneumonia, *Klebsiella* can cause infections of the urinary tract, lung, and central venous catheters in high-risk newborns and immunocompromised older children.²¹

BACTERIOLOGY

Klebsiella organisms were named for Edwin Klebs, the noted German bacteriologist.¹⁰⁸ Distinguishing features of *Klebsiella* spp. include the absence of motility and the presence of a polysaccharide capsule that gives rise to large mucoid colonies on solid media. However there was one recent report of a *K. pneumoniae* clinical isolate that demonstrated a swim-like motility by electron microscopy and staining revealing polar

flagella.²³ The organisms are oxidase-negative and citrate-positive; they ferment inositol and hydrolyze urea but do not produce ornithine decarboxylase or hydrogen sulfide. Acetoin and 2,3-butanediol predominate over acidic end products during sugar fermentation (positive result on the Voges-Proskauer test). Four species of *Klebsiella* commonly are agreed on by microbiologists: *K. pneumoniae* (the most common human pathogen), *K. oxytoca* (a less common human pathogen), *K. terrigena*, and *Raoultella planticola*. Previously *R. planticola* was recovered almost exclusively from soil and aquatic environments; reports now suggest that this organism may be a relatively common neonatal pathogen in some parts of the world.^{116,147} *R. planticola* isolates with increased drug resistance have been reported worldwide. A 4-year retrospective study of 42 isolates listed the bloodstream as the most common site of *Raoultella* infection, with indwelling catheters and intensive care unit

(ICU) stays as risk factors.³⁷ *R. planticola* may express virulence factors similar to those of *K. pneumoniae*.¹¹⁷ Recently the frequency of reports of *R. planticola* infection has increased likely due to increased identification. Organisms are defined serologically by their capsular polysaccharide (K antigens) and lipopolysaccharide (O antigens). Significant cross-reactivity exists between the capsule of some pneumococci (e.g., 19F) and *Klebsiella*.⁸⁸ The reader is referred to a review by Podschun and Ullman¹¹⁹ for a detailed description of *Klebsiella* spp.

EPIDEMIOLOGY

Friedländer⁴⁸ proposed that *K. pneumoniae* was the most common cause of community-acquired pneumonia, an observation that was refuted by Fraenkel's⁴⁶ observations on pneumococcal pneumonia. *K. pneumoniae* accounts for fewer than 10% of hospitalized cases of pneumonia in adults.²⁴ *Klebsiella* spp. were historically thought to cause serious infection in immunocompromised hosts, but recent hypervirulent strains have caused increased infections in immunocompetent patients.¹¹⁰ *Klebsiella* spp. are in greatest evidence as opportunistic nosocomial pathogens of the urinary tract, respiratory tract, biliary tract, and bloodstream. In one survey of the Centers for Disease Control and Prevention (CDC), the infection rate of nosocomial *K. pneumoniae* was 16.7 infections per 10,000 patients discharged.⁶⁹ Hand carriage generally is regarded as the most common mode of transmission.⁵² Environmental sources of *Klebsiella* spp. include contaminated blood pressure monitoring equipment,¹²⁵ ventilator traps,⁵² dialysate,⁸² ultrasound coupling gel,⁵⁰ dextrose solution,⁸⁶ and hand disinfectant.¹²⁸ The emergence of plasmid-mediated, β -lactamase resistance can be responsible for the rapid spread of resistant organisms to susceptible patients in ICUs.^{13,15} Outbreaks may be complex; patient-to-patient transmission of epidemic strains containing different plasmids may be interspersed with sporadic, nonepidemic *Klebsiella* infections.¹⁵

Klebsiella spp. are second only to *Escherichia coli* as causes of sepsis,⁵¹ with the highest rates of infection being reported from larger hospitals affiliated with medical schools. Strains expressing extended-spectrum β -lactamases (ESBL) may become endemic and may present a complex and diverse pattern of production of enzymes with resistance to β -lactamase inhibitors.^{40,45} Although broad-spectrum resistance to β -lactams and carbapenems⁹² has been described, previous longitudinal studies have shown that the frequency of ESBLs in *K. pneumoniae* isolates is decreasing.¹³¹ Hypervirulent strains and multidrug-resistant isolates have evolved separately but are both contributing to increased morbidity. The dissemination of resistance is due to mobile elements that may also transfer increased virulence.⁶⁰ In 2012, 4% of acute care hospitals reported at least one carbapenem-resistant enterobacteriaceae (CRE) hospital-acquired infection, an increase from 1% in 2001. Carbapenem resistance is increasing, but most CRE infections are still health care associated.²⁶

Klebsiella spp. commonly are highlighted as pathogens of debilitated adults and alcoholics,⁷⁶ but by 1985, nearly 50% of reported outbreaks of *Klebsiella* were in neonatal ICUs.⁶⁹ Outbreaks in newborns continue to occur frequently worldwide.^{2,10,31,39,62,114,127} Most outbreaks in newborns have been associated with *K. pneumoniae* infection, but scattered outbreaks of *K. oxytoca* infection in nurseries also have been reported.^{9,146} A high percentage of infants in ICUs may become colonized with hospital strains of *Klebsiella*.⁵⁸ In one longitudinal study in which weekly rectal swabs were cultured, 80 of 368 (22%) neonates in an ICU harbored ESBL-producing *Klebsiella* spp.¹⁸ Infecting organisms have been isolated from care providers and from mothers of colonized infants.³¹ One report described an outbreak among newborns associated with infestation of a neonatal unit by cockroaches colonized with infecting *Klebsiella* strains.³² *Klebsiella* may spread from newborn units to adult units; interhospital and international spread of resistant strains has been described.^{30,39,135} In a newer report, 31 neonates became colonized, 10 were infected, and five died from a neonatal ICU (NICU) outbreak in Maryland. Understaffing of an overcrowded NICU was thought to be important in the genesis of the outbreak.¹⁴⁵ In another NICU outbreak, the use of proton pump inhibitors and prior receipt of third-generation cephalosporins were identified as the principal risk factors for colonization and infection with an ESBL-producing strain.⁵⁵ Outbreak control usually depends on

cohorting, careful hand washing, and intensive cleaning. However *K. pneumoniae* isolates that are extremely antibiotic resistant also may be more resistant to chlorhexidine; cleaning with this agent in such cases may provide a selective advantage to the resistant strain.¹⁰⁵

CRE outbreaks have increased over the past 2 decades, and plasmid-encoded carbapenem hydrolyzing enzymes have the potential for rapid dissemination. *K. pneumoniae* carbapenemases (KPC) are responsible for most carbapenem resistance in the United States. A CDC report from 2013 examined the resistance of enterobacteriaceae isolates in the United States and found that it was increasing and that most infections with CRE were associated with health care exposure.²⁶ New Delhi metallo- β -lactamase (NDM)-producing CRE isolates were shown to be increasing in the United States.²⁷ OXA-48 was first identified in Turkey in 2001, but was retrospectively identified in isolates in the United States from 2009 and 2012,⁹³ and OXA-48-like carbapenemases were increasingly identified in the United States from 2010 to 2015.⁹³ In 2012, the spread of the bla (OXA 48) gene was linked to a single self-transferable plasmid that did not carry any additional resistance genes and only demonstrated decreased susceptibility to carbapenems, not broad-spectrum cephalosporins.¹²⁰ OXA-48-like carbapenemase-producing enterobacteriaceae hydrolyze penicillins and carbapenems and differ by one to five amino acids from the OXA-48-like genes associated with a plasmid.¹²⁰ These variants can combine variability and demonstrate high levels of resistance to carbapenems. Verona integron encoded metallo β -lactamase-producing Enterobacteriaceae were identified in a NICU and in an adult ICU outbreak in Kentucky in 2015, with isolates from six different patients. However, most of these were *Enterobacter*, with one *E. coli*, one *Raoultella*, and one *K. pneumoniae*.¹⁴⁸

Ribotyping, pulsed-field gel electrophoresis, and DNA amplification techniques have proved valuable in characterizing *Klebsiella* strains associated with outbreaks.^{90,137,138} Whole-genome sequencing was compared with pulsed-field gel electrophoresis in one outbreak study. Neither could definitively determine relatedness, but whole-genome sequencing identified an additional plasmid.¹⁴⁹ Experimental techniques include multiplex real-time polymerase chain reaction, which can identify carbapenem-resistant *K. pneumoniae* strains in 2 hours.¹⁴⁴ The modified Hodge test is used in resource-limited settings and works quite well at identifying organisms that produce carbapenemases.⁵ Different ribotypes that share plasmids conferring antibiotic resistance can be responsible for pediatric infections in a particular institution.¹⁵ Strains expressing ESBL may become endemic and may present a complex and diverse pattern of production of enzymes with resistance to β -lactamase inhibitors.^{40,45} Active surveillance, carrier cohorting, and increased barrier protection resulted in a decrease in the frequency of KPC-producing *K. pneumoniae* in one Greek hospital.¹²¹

PATHOPHYSIOLOGY

Pneumonias caused by *Klebsiella* most commonly arise from colonization of the upper respiratory tract, followed by aspiration of organisms to the lower respiratory tract. Some degree of gram-negative oropharyngeal colonization is a normal finding in newborns. The oropharynx of nearly one-third of healthy newborns is colonized by gram-negative rods, including *Klebsiella*, by the time infants reach 1 month of age; colonization rates generally are lower in breast-fed infants.¹² Antibiotic pressure in high-risk newborns and older children has been observed to promote overgrowth of *Klebsiella*.^{14,134} Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults; oral colonization with gram-negative rods is increased during illness,⁷³ after postoperative viral infections,^{72,124} and in debilitated adults.⁹⁴ Increased adherence of gram-negative rods to oropharyngeal cells contributes to increased colonization.⁷² Elastase made by polymorphonuclear cells contributes to such colonization by reducing the fibronectin coating of sugar receptors.³⁵ The capsule plays an initial role in interactions of epithelial cells but is not required for an adhesin interaction with the cell surface.⁴³ Adherence properties may be affected by plasmid content³⁸ and may be transferred between *E. coli* and *K. pneumoniae*.⁶⁸

In animal models of sepsis, capsular polysaccharide (K antigens) is a virulence factor; monoclonal antibodies to the K antigens reduce the

severity of illness in mice.⁸⁷ In a mouse model of urinary tract infection (UTI), the K antigens seemed to be more important in infection than the lipopolysaccharide (O antigens), and clinical strains deficient in lipopolysaccharide retained virulence by resistance of capsule to complement.^{4,22} In one series of adult patients, capsular type K2 frequently was associated with asymptomatic bacteriuria and cystitis, but not pyelonephritis; the presence of type 1 fimbriae bore a closer relationship to upper UTI.¹¹⁸ In a retrospective study, patients bacteremic with hyperviscous strains were more likely to develop invasive localized disease, such as liver abscess, meningitis, pleural empyema, or endophthalmitis.⁸⁹ Patients bacteremic with the hypermucoviscous phenotype are more likely to come to the hospital from the community and less likely to have underlying disease states, suggesting increased virulence.⁷⁷ Liver abscess is almost always caused by hypermucoviscous organisms⁴⁴; surprisingly, disruption of the genes that produce this phenotype did not affect serum sensitivity in vitro and did not alter abscess formation in a mouse model.⁸³ In another study, the lipopolysaccharide O1 was found to be important; O1 serotypes had higher serum resistance and mutation of the O1 gene greatly reduced the virulence of the organism in a mouse model.⁵⁶ Neutrophils play an important role in clearance of *Klebsiella*, and phagocytosis is augmented by leukotrienes.⁹⁵

CLINICAL MANIFESTATIONS

Klebsiella infection shows little clinical distinction from diseases produced by other enteric pathogens. The organism generally is less common than group B streptococcus or *E. coli* as a cause of early-onset or late-onset infection in newborns.^{53,98} Investigators from Spain,⁶² however, reported one 7-year interval in which *K. pneumoniae* was the most common cause of bacteremia in newborns. In Yemen, gram-negative rods accounted for almost all of 90 cases of neonatal sepsis; *E. coli* outnumbered *K. pneumoniae* by only one case.³ Risk factors for neonatal *Klebsiella* infection include prematurity, presence of indwelling catheters, previous antibiotic treatment, and parenteral nutrition.¹²⁷ Infection in newborns is characterized by typical features of pneumonia, sepsis, and meningitis.⁹⁸ In one unusual case, *K. pneumoniae* bacteremia manifested on day 4 of life as a morbilliform maculopapular exanthem, more severe on the face. The infant was afebrile, but the mother had had fever in the peripartum period, and the amniotic fluid had been meconium stained.²⁵ There was also one reported case of confirmed ophthalmia neonatorum in a healthy newborn, and urgent treatment was recommended.⁸⁵

Although hepatic abscesses have been associated principally with adults with poorly controlled diabetes mellitus, one case report described a 32-week-gestation neonate with *K. pneumoniae* sepsis who developed a liver abscess large enough to be noted on physical examination as an abdominal "lump."¹³⁹ In adults, hepatic abscess occasionally is complicated by endophthalmitis or central nervous system infection, with devastating outcomes. A study from Taiwan found that infection with genotype K1 was the only significant risk factor for these complications.⁴² This series also revealed that eight of 19 (42%) of the complicated K1 strain infections occurred in patients without identifiable underlying medical disease.⁴² Other investigators have emphasized that serotype K2 also can be virulent in patients with liver abscess.⁴⁹ Careful study of the pathophysiology and epidemiology of complicated *K. pneumoniae* liver abscesses is ongoing, and the picture is likely to continue to be clarified.

Klebsiella spp. have been isolated commonly from blood and peritoneal fluid in outbreaks of necrotizing enterocolitis.^{54,102} Less common manifestations in infants include toxic epidermal necrolysis,^{59,113} conjunctivitis,⁸⁴ parotitis,²⁹ retropharyngeal abscess,³³ subdural hematoma,¹⁰⁷ psoas abscess,⁶ and renal abscess.¹⁴³

Klebsiella is an unusual cause of infection in an otherwise healthy older child. The classic Friedländer pneumonia that occurs in debilitated adults⁴⁸ is rare in children. The identification of pulmonary infection should suggest the possibility of underlying immunodeficiency or significant malnutrition, if not suspected previously.^{67,74} If pneumonia caused by *Klebsiella* does occur, progression to lung abscesses should be anticipated.

Lung abscesses may develop within days to weeks after *Klebsiella* infection. Formation of abscesses occurs more frequently during *Klebsiella* pulmonary infection than during any other community-acquired infection.²⁴ A rare but devastating outcome is massive pulmonary gangrene—the rapid total destruction of part of the lung presumed to be due to vascular compromise. This complication is heralded by radiographs that show small cavities that later coalesce into a large cavity with an intracavitary mass of necrotic lung.^{104,109} Some researchers speculate that *Klebsiella* lung infection is accompanied by coincident anaerobic infection that contributes to or is primarily responsible for the pathologic process.²⁴

Catheterization of the urinary tract can be associated with urinary tract *Klebsiella* infection, but bacteremia is an uncommon complication in an immunocompetent child.^{36,91} Asymptomatic bacteriuria is also frequently encountered. In one retrospective study, a carbapenem-resistant *Klebsiella* strain was isolated on a urine culture in an asymptomatic patient. This did not lead to increased risk of UTI or other *Klebsiella* infections.¹²³ Approximately 10% of nosocomial UTIs observed in infants after surgery are caused by *Klebsiella*.³⁶ Focal renal infection progressing to renal abscess has been described.⁸¹ *K. pneumoniae* bacteremia has been associated with lesions of the gastrointestinal tract, presence of an indwelling central venous catheter, and neutropenia. Patients with short-bowel syndrome seem to be at greater risk than are patients with inflammatory bowel disease or malignancy for development of catheter-associated *Klebsiella* or *Enterobacter* bacteremia. *K. pneumoniae* was a constituent of polymicrobial bacteremia in 15 such patients (26%).¹⁷ Mortality rates have ranged from 5% to 20%, with higher death rates occurring in children infected with an aminoglycoside-resistant strain.^{16,69} Pneumonia, shock, and disseminated intravascular coagulation are poor prognostic factors in children with underlying malignancy. Rare clinical presentations include multifocal osteomyelitis⁸⁰ and endophthalmitis.⁹⁶ Pediatric recipients of solid organ transplants may have high rates of acquisition of drug-resistant *Klebsiella*.¹²⁶ *Klebsiella* spp. have been described as a frequent pathogen in children and adults with sickle-cell disease in West Africa.¹

Of four patients who received organ transplants from people who had been infected with KPC-producing *K. pneumoniae*, one developed invasive infection despite tigecycline prophylaxis.⁸ *K. pneumoniae* was the most common cause of bloodstream infection in children undergoing liver transplantation in Korea, accounting for 22% of all infections.¹²⁹ In New York City, *K. pneumoniae* was the second most common etiology of infection among adult liver transplant recipients. The mortality rate was 71% among those who contracted KPC-positive strains; the odds ratio for death was 4.9 for those with the KPC-producing isolates.⁷⁸

Of six patients with clinical and colonoscopic findings suggestive of antibiotic-associated hemorrhagic colitis (pseudomembranous enterocolitis) but negative evaluation for *Clostridium difficile*, five had stool cultures positive for *K. oxytoca*.⁶⁵ All five patients had been receiving penicillin therapy. *K. oxytoca* was cultured from only 1.6% of 385 healthy controls. Additionally the disease could be reproduced in a rat model when rats were inoculated with *K. oxytoca* and administered amoxicillin-clavulanate, but disease was not seen if rats were not given the injection and the antibiotic treatment.⁶⁵

DIAGNOSIS

Klebsiella spp. characteristically grow as large mucoid colonies on MacConkey agar. Citrate-containing media can be used to facilitate isolation of *Klebsiella* strains because these organisms can use citrate as a sole carbon source.¹⁰⁸ Serotyping with specific antisera usually is determined by counterimmunoelectrophoresis or a Quellung test.¹¹ In situ hybridization techniques have been used to identify *Klebsiella* in phagocytes from blood specimens,⁹⁷ and restriction-enzyme analysis and ribotyping of clinical isolates have been used to characterize nosocomial spread of antibiotic-resistant strains.^{15,56,57} Conventional, commonly used microbiologic methods may misidentify some *Klebsiella* spp., particularly *R. planticola* and *K. terrigena*.¹⁰³ Rarely blood cultures have required longer than 72 hours of incubation for radiometric detection of *Klebsiella*.⁹⁹

TREATMENT

Empirical antimicrobial therapy should be guided by an understanding of antimicrobial susceptibilities of *Klebsiella* in the hospital. Therapy with a cephalosporin plus an aminoglycoside (rather than a cephalosporin alone) has been associated with a more favorable outcome in patients with cancer who are infected with susceptible strains.¹⁶ Antimicrobial therapy of *Klebsiella* spp. is made problematic, however, by the resistance to penicillins and cephalosporins conferred by ESBLs.^{13,15,19,61} *Klebsiella* with ESBL are widely distributed, and regional differences in susceptibility occur.⁷⁵ As described earlier, carbapenems have also become ineffective in cases of CRE; plasmid-encoded carbapenemases pose a major public health concern. Outer membrane protein changes and porin deficiencies of some strains can augment resistance to third-generation cephalosporins.^{7,130} Some investigators have reported significant correlation between production of ESBL and resistance to ciprofloxacin.^{112,136} Plasmid-mediated resistance to aminoglycosides also is common.^{9,31,51,106} Endocarditis isolates that developed resistance to piperacillin-tazobactam and to ciprofloxacin during therapy have been reported.¹⁵⁰

In cases of CRE, aminoglycosides may be a possible treatment if strains are susceptible and no cell wall active agent is available. Aminoglycosides were associated with a 70% 30-day survival rate in bacteremia cases.¹⁴¹ Prediction of response to aminoglycosides depends on presence of both KPC and ESBL in *Klebsiella*. Resistance to gentamicin and tobramycin was as high as 100% for isolates that were both KPC and ESBL positive. These isolates were more likely to contain aminoglycoside-modifying enzymes.^{56,57} Aminoglycoside monotherapy is more likely to be successful when infection is limited to the urinary tract. There may be a role for plazomicin in some cases.

Effective treatment of multidrug-resistant isolates sometimes requires creativity or use of antibiotics no longer commonly employed. In one case report, a 15-year-old girl developed bacteremia with a meropenem-intermediate strain; bacteremia persisted despite thrice-daily administration of meropenem combined with gentamicin, to which the isolate was sensitive. Clearance was achieved eventually with meropenem administered as a continuous infusion.⁴¹ In another case, bacteremia and peritonitis developed in a patient on continuous ambulatory peritoneal dialysis; infection persisted despite removal of the catheter and treatment with meropenem and amikacin (to which the isolate was intermediately resistant). Cure required a switch to intravenous polymyxin B.¹¹¹ Treatment of carbapenem-resistant strains is even more difficult. In vitro, the combination of doripenem and colistin produced bactericidal activity in 75% and synergy against 50% of colistin-resistant KPC-positive strains.⁷⁰ Treatment failures in carbapenem-colistin combination therapies are much more likely if isolates show resistance in vitro, with colistin having a minimum inhibitory concentration (MIC) of more than 2 and doripenem a MIC of more than 8 in KPC-producing strains. This resistance may also depend on the absence of other porin mutations.¹⁴² In gentamicin-susceptible, KPC-2-producing isolates with minor ompK36 mutations, doripenem-colistin was inferior to gentamicin alone or combinations of doripenem-colistin and gentamicin. This suggests that genotyping and susceptibility testing may be necessary to select an effective treatment regimen.²⁸ In an animal model, isolates that were carbapenem-resistant because of OXA-48 were more sensitive to ceftazidime than to piperacillin-tazobactam, imipenem, ertapenem, or cefotaxime.¹⁰¹ New approaches to the treatment of so-called pan-resistant strains include the novel β -lactamase inhibitor MK-7655⁶⁴ (Relebactam) and an antibacterial “designer peptide” called Api88, which binds a chaperone protein and rescues mice from lethal challenge.³⁴ Ceftazidime-avibactam has been shown to be potent against organisms that are resistant to most other antibiotics, including KPC-producing strains.^{133,140} Ceftazidime is a β -lactam, and avibactam is a novel non- β -lactam/ β -lactamase inhibitor. It is recommended for use in combination with other agents due to risk of multiple mechanisms of resistance, unless susceptibility testing can be performed.

Antibiotic pressure is important in increasing the risk for development of resistant isolates.¹²² In some nursery outbreaks, switching from gentamicin to amikacin has been associated with return of the susceptibility of *Klebsiella* isolates to gentamicin.^{9,63} Imipenem or the combination of piperacillin and tazobactam may show good antimicrobial activity against multiply-resistant organisms.^{71,115,122} The combination of β -lactamase and porin deficiency has been associated with resistance

to imipenem,²⁰ and hyperproduction of some β -lactamases can limit the effectiveness of β -lactam/ β -lactamase inhibitor combinations.⁴⁷ Experience with ciprofloxacin in young children is limited because of observations of irreversible cartilage injury in juvenile laboratory animals after administration of this quinolone. Successful treatment of a multidrug-resistant *K. pneumoniae* has been reported in a preterm infant, however, without observable short-term adverse effects.⁷⁹ Avoidance of excessive antibiotics is also important due to rapid development of resistance, and, for carbapenem-resistant *K. pneumoniae* limited to the urinary tract, doxycycline monotherapy may be effective.¹²³ Strict adherence to infection control policies that promote restricted antibiotic use, cohorting, and hand washing may help to prevent the spread of resistant *Klebsiella* strains.^{9,31,58,100,132}

Acknowledgments

We thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Similar to *Proteus* and *Providencia* spp., *Morganella morganii* has emerged as an important nosocomial pathogen, most often associated with urinary tract or wound infections. Although most descriptions of infection are in adults, infections in children do occur.

HISTORY

In 1905, Castellani isolated and described a bacterium that caused typhoid-like fever. He later called this isolate and two other identical strains *Bacterium columbense*. In 1906, Morgan described a nonlactose fermenting organism associated with summer infantile diarrhea occurring in Germany, Philippines, and the United States. This organism was known as Morgan's bacillus until Winslow and colleagues named it "*Bacillus morganii*" in 1919. Two decades later, Rauss demonstrated that *B. morganii* had similar spreading phenomenon exhibited by *Proteus* species and renamed this bacterium "*Proteus morganii*." Fulton proposed a new genus called *Morganella* after discovering that *B. columbense* and *P. morganii* were the same species in 1943. However, *B. columbense* was reclassified as *Escherichia coli* leaving *M. morganii* solitary within its genus. As a result, *M. morganii* was relegated to the genus *Proteus*. Finally, the organism was elevated to genus rank in 1978 after molecular phylogenetic analysis revealed genetic differences from *Proteus*, with which it is otherwise biologically similar.⁴⁰

BACTERIOLOGY

M. morganii (formerly *Proteus morganii*) is a motile gram-negative bacillus commonly found in the feces of humans, other mammals, and reptiles.⁴³ Most strains do not ferment lactose. *M. morganii*, *Proteus* spp., and *Providencia* spp. are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Similar to *Proteus* and *Providencia* spp., *M. morganii* produces urease, but this enzyme is unrelated genetically and serologically to urease produced by the other two genera.^{24,43} In contrast to *Proteus* spp., neither *Providencia* spp. nor *M. morganii* shows swarming activity on 1.5% agar⁴³; *M. morganii* is ornithine positive, whereas *Providencia* spp. are ornithine negative. *M. morganii* organisms do not hydrolyze gelatin and do not produce hydrogen sulfide. For a detailed discussion of taxonomy and characterization of *M. morganii*, the reader is referred to the review by O'Hara and colleagues.⁴⁰

EPIDEMIOLOGY

Similar to *Proteus* and *Providencia* spp., *M. morganii* organisms commonly are found in soil, sewage, and manure. Similar to *Proteus mirabilis*, *M. morganii* often invades urinary bladder catheters and surgical wounds; patients in adult inpatient surgical units have the greatest risk for colonization and infection.¹ Institutionalized elderly patients also are infected frequently with these organisms. Urinary tract colonization with *M. morganii* accompanying groin skin colonization in elderly individuals may account for the greater frequency of urinary tract infections in this population.¹⁸ *M. morganii* accounted for nearly 10% of 145 consecutive complicated, multidrug-resistant urinary tract infections in one study.¹³ *E. coli* and *P. mirabilis* account for most urinary tract infections in children, but *M. morganii* has been implicated in some cases of cystitis and pyelonephritis. In contrast to well-described nursery epidemics of *P. mirabilis* infection,^{3,8} no *M. morganii* neonatal outbreaks have been described, and infections of the central nervous system are rare in newborns.^{16,35,57} A fatal case of early-onset sepsis in which both the mother's lochia and the neonate's blood were culture positive has been

reported; the baby died at 17 days of age despite appropriate antimicrobial therapy.⁴¹ Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analyzing outbreaks.⁴⁵

PATHOPHYSIOLOGY

Factors that predispose the urinary tract to invasion by *P. mirabilis* and *Providencia* spp. also may favor *M. morganii* colonization and infection. These organisms all split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.^{6,37} The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH compared with *M. morganii* may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.⁵²

CLINICAL MANIFESTATIONS

Urinary tract infection with *M. morganii* often is associated with an elevated urinary pH. Urolithiasis can occur, although perhaps less frequently than during *P. mirabilis* infection.⁴ *M. morganii* has been recovered from less than 10% of adult bacteremic episodes, but mortality rates have exceeded 20%.¹ Approximately three fourths of all cases of adult *M. morganii* bacteremia are hospital associated.²⁷ In a series of 132 patients with bacteremia from Proteaceae, preexisting biliary or hepatic disease (especially the presence of biliary drainage catheters) was associated with *Morganella* bacteremia.²⁷ In a series of 73 patients with *Morganella* bacteremia in Taiwan, 92% had at least one underlying disease, the most common of which was solid tumor. The only independent risk factor for mortality was inappropriate antibiotic treatment.³¹ Other reported complications identified in immunocompromised or instrument-fitted patients include meningitis,^{21,33} pericarditis,³⁸ arthritis,^{26,50} osteomyelitis,²⁹ empyema,²² spontaneous bacterial peritonitis,²² peritoneal dialysis-related peritonitis,^{28,55} intratesticular abscess,⁵⁹ prostatitis,³² otitis media,¹⁹ and skin infection.² Many cases of postoperative *M. morganii* endophthalmitis and panophthalmitis have been reported, as have rare cases of endogenous endophthalmitis, all in adults.^{12,56,58,60}

M. morganii has been recovered alone or in combination with other organisms from surgical wounds¹³ and soft tissue abscesses in children.^{7,14} A 12-year-old with *M. morganii* meningoencephalitis secondary to chronic otitis, whose immune system was apparently normal, has been reported.³⁹ Septic arthritis with *M. morganii* was described in an otherwise healthy 23-month-old.⁴⁹ Another rare manifestation of *M. morganii* infection was pericarditis, seen in a child with X-linked agammaglobulinemia.¹⁰ A 3-year-old boy developed hemorrhagic bullae and necrotizing fasciitis after being scratched by a chicken; cultures grew both *M. morganii* and enterococci.³⁰ Meningitis and brain abscess have been described.^{35,42,57} Approximately 13 cases of neonatal sepsis with *M. morganii* have been reported in the literature.^{9,35,36} Mortality rates exceed 30% in this age group. Lower gestational age and smaller birth weight were associated with higher morbidity and mortality.⁹ In four cases of early-onset neonatal sepsis with *M. morganii*, premature rupture of membranes and maternal receipt of antepartum amoxicillin were documented.^{5,9,17}

DIAGNOSIS

M. morganii produces a reddish brown pigment when cultured on nutrient media supplemented with 5% tryptophan.⁴³ Production of urease and deamination of tryptophan help to distinguish this bacterium from other organisms. In contrast to the closely related *Proteus* and

Providencia spp., *M. morganii* generally ferments only glucose and mannose and does not produce a red color on lysine iron agar.⁴³ *M. morganii* may be missed or mistaken for other organisms in the common circumstance of polymicrobial infection in a catheterized patient. In one series, *M. morganii* was among the most common bacteriuric species in patients on long-term catheterization but commonly was missed by reference laboratories.¹⁵ Automated systems provide rapid and reliable genus and species-level identification for *Morganella* spp.⁴⁷ The clinical laboratory should be directed to look for this organism, particularly in circumstances of nosocomial urinary tract infection and sepsis.

TREATMENT

Effective treatment of local infections or septicemia relies on appropriate choice of an antibiotic, often including an aminoglycoside, combined with removal of invasive devices, surgical debridement, and drainage of abscesses, as necessary. Antimicrobial susceptibility can vary widely among *M. morganii* and the related *Proteus* and *Providencia* strains, emphasizing the importance of species identification and susceptibility testing.^{25,44} Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.³⁴ Most isolates are intrinsically resistant to ampicillin and first- and second-generation cephalosporins. Some carry a chromosomal broad-spectrum AmpC β -lactamase that can be stably derepressed on treatment with third-generation cephalosporins, similar to *Enterobacter* spp., although it appears that this problem arises much less frequently among *Morganella* isolates.¹¹ Most urinary tract infections respond to treatment with third-generation cephalosporins. Failure to clear bacteriuria should alert the physician to the possibility of urolithiasis or structural abnormality⁴; stone removal or surgical correction of anatomic defects often is required for cure. The approach to the treatment of sepsis or serious infection of sites other than the urinary tract should be considered carefully in light of local susceptibility patterns, keeping in mind that isolates with AmpC β -lactamases may seem to be sensitive to cephalosporins on initial testing but develop resistance during therapy. Treatment failure, with prolonged culture-positive ventriculitis, has been described in an infant with *M. morganii* meningitis after initial therapy that included cefotaxime led to stable derepression of an AmpC β -lactamase, showing the potentially devastating clinical relevance of this phenomenon.⁵³ Data from the SENTRY Antimicrobial Surveillance Program has shown reduced susceptibility to imipenem for *M. morganii* in the United States.⁴⁶ Carbapenemases (including IMP-1, VIM-1, NDM-1, and OXA-48) and plasmid-mediated quinolone resistance gene *qnrS1* activity have been reported among *M. morganii*.^{20,23,48,51} Addition of avibactam enhances the activities of aztreonam, ceftaroline, and ceftazidime against resistant Enterobacteriaceae.⁵⁴

Acknowledgments

We thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Proteus

107

Randall G. Fisher

BACTERIOLOGY

Proteus spp. are motile, gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Rapid and abundant production of urease further differentiates *Proteus* spp. from *Providencia* spp.³⁷ *Proteus vulgaris* and *Proteus mirabilis* tend to form a thin, spreading

growth (swarm) on the surface of moist agar media, often overgrowing other bacterial isolates. They also produce hydrogen sulfide and liquefy gelatin. *P. mirabilis* is distinguished from other *Proteus* spp. (e.g., *P. vulgaris*) by its inability to produce indole from tryptophan. Most indole-negative clinical *Proteus* isolates are classified by laboratories as *P. mirabilis*; however, in one study, eight of 61 were found to be *P.*

Abstract

Proteus spp. are pathogens that are associated increasingly with pediatric illness. Neonatal meningitis and pediatric urinary tract infections are the most common childhood conditions in which these organisms are isolated, but infections of other organ systems have been described.

Keywords:

Proteus
neonatal meningitis
urinary tract infection

penneri when extensive biochemical testing was performed.³⁵ Disparate DNA content and anomalous biochemical and serologic reactions have caused *Proteus morganii* to be renamed *Morganella morganii* (see Chapter 106),³⁷ and both terms for this organism appear in the clinical literature. For detailed discussion of taxonomy and characterization of *Proteus* spp., the reader is referred to the review by O'Hara and colleagues.⁴⁹

EPIDEMIOLOGY

Proteus spp. commonly are found in soil, sewage, and manure. Although they are normal inhabitants of the colon and perineum, their numbers can be increased in individuals receiving antibiotic therapy.³³

First reported by Buisine and Henninot in 1949,¹³ neonatal meningitis caused by *P. mirabilis* accounts for approximately 4% of all neonatal meningitis cases.⁴⁵ Outbreaks in nurseries have been attributed to contaminated equipment and human carriers. Vertical transmission from mother to infant has been confirmed by DNA fingerprinting and ribotyping methods.¹⁰ In Becker's series⁷ of *P. mirabilis* neonatal meningitis, all affected infants came from the same nursery and all were exposed to mist from an apparatus that yielded *P. mirabilis*. The importance of hand carriage was well documented by Burke and associates¹⁴; neonatal umbilical colonization and invasive disease were linked to a single nurse from whom *P. mirabilis* was cultured from her hands, rectum, and vagina. Ribotyping is a sensitive method for molecular characterization of isolates and may aid in analyzing outbreaks.⁵³

Proteus infection after the first few months of life most commonly involves the urinary tract. Although *Escherichia coli* accounts for most urinary tract infections in children, *Proteus* spp. commonly are implicated in reported series of cystitis and pyelonephritis^{9,24,34,50,73}; in a large pediatric series, they were the third most common cause of urinary tract infection, after *E. coli* and *Klebsiella pneumoniae*.¹¹ *P. mirabilis* is the most common species of *Proteus* isolated: it has been cultured more frequently from the urethra of uncircumcised than of circumcised male infants and replaced *E. coli* as the most prevalent pathogen in one consecutive series of male patients presenting with initial urinary tract infection.^{34,74}

Urinary tract infection with *Proteus* spp. is one of the most common presenting signs of urolithiasis in children,²⁰ and *P. mirabilis* supplants *E. coli* as the major urinary tract pathogen in children prone to renal stone formation.⁹ Diagnosis of greater than 50% of pediatric urolithiasis cases is based on preceding urinary tract infection, and *Proteus* is responsible for 65% of these infections.⁹ Isolation of this organism as a pathogen on urine culture should alert the physician to the possible presence of a urinary tract stone.

PATHOPHYSIOLOGY

Most cases of central nervous system infection caused by *Proteus* spp. occur in neonates and are thought to arise by bacteremic spread of the organism to the brain or meninges. Contiguous spread to the brain from localized infections is reported occasionally.^{44,62} As is the case with *Citrobacter* meningitis, a propensity for formation of abscesses of the central nervous system remains unexplained. Rabbit models of *P. mirabilis* meningitis have shown that in vivo concentrations of gentamicin necessary to produce bacterial killing are 10 to 30 times higher than the concentrations predicted from in vitro susceptibility testing.⁶⁹ Reduced aminoglycoside effect may be secondary to depressed cerebrospinal fluid pH associated with *P. mirabilis* infection.⁶⁹ Whatever the mechanism, lack of effective antimicrobial activity in the ventricles accounts partly for the persistence of organisms at these sites.

Crystallization of urinary catheters and stents leads to obstruction of outflow of urine. Urease produced by *Proteus* infection causes calcium phosphate and magnesium phosphate to precipitate and accumulate in the catheter lumen.⁶⁸ This process is less likely to occur when the urine is dilute and acidic.⁶⁸ In vitro, increasing the concentration of magnesium, calcium, and phosphate strongly intensifies crystallization, although decreasing their concentrations below physiologic levels has no effect on crystal formation.⁷⁰ Mannose-resistant/*Proteus*-like fimbriae (often shortened to MR/P fimbriae) are important in the formation of biofilms on catheter material⁵⁷ and also, apparently, in attachment and cytotoxicity.⁵⁹ *Proteus* isolates obtained from catheter-associated urinary tract infection

have increased swarming motility and form biofilms more readily than *Proteus* isolates from stool of healthy volunteers.²⁸ Methods of preventing crystallization of catheters include coating them with agarose⁶⁷ and impregnating them with chlorhexidine and triclosan.²³

Numerous factors may predispose the urinary tract to invasion by *Proteus* spp. *Proteus* spp. split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.^{12,47} The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH when compared with *M. morganii* may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.⁶¹ Biochemically complex struvite (MgNH₄PO₄) stones provide a refuge for *Proteus* organisms and form a barrier to effective antimicrobial therapy.⁹ Formation of struvite stones is a major cause of urinary bacterial persistence in women without azotemia,⁶⁶ and a similar case probably can be made for pediatric patients with urolithiasis. *P. mirabilis* ureases showed lower affinities for substrate but hydrolyzed urea 6 to 25 times faster than enzymes from other species, which may explain the frequent association of this species with formation of stones.³⁰

Organisms have been shown to be taken up by human renal epithelium, by an actin-independent mechanism.¹⁶ Pili may enhance the virulence of *Proteus* in pyelonephritis by increasing adherence of organisms to the renal pelvis.^{57,63} Flagella have been implicated in the spread of this organism in the urinary tract⁴⁰; the ability to invade host uroepithelial cells is coupled closely with the ability of *P. mirabilis* to differentiate into hyperflagellated, filamentous swarm cells capable of rapid spread on the surface of moist agar media.⁴ The role of fimbriae as a factor predisposing to ascending infection is less clear.^{6,43} Swarming behavior might inherently assist ascending colonization of the urinary tract, as shown in a mouse model of infection.⁵ A putative gene regulator for swarming behavior (RsbA) may act to identify environmental conditions that favor swarming.⁸ The reader is referred to the review by Rozalski and colleagues⁵⁸ for a more in-depth review of *Proteus* virulence factors.

A growing body of literature suggests that adult rheumatoid arthritis may be triggered by infection of the urinary tract with *Proteus* spp. In one study, increased levels of total and class-specific immunoglobulin G antibodies directed at three *Proteus* peptides were found in patients with rheumatoid arthritis but not in control subjects.⁵⁶ Patients with active disease had measurable IgM, and a positive correlation was found between antibody indices and inflammatory markers.⁵⁶ This association is still speculative and is being investigated; at this time, no suggestion has been made that juvenile idiopathic arthritis is related in any way to *Proteus* infection.

CLINICAL MANIFESTATIONS

P. mirabilis can produce a broad spectrum of symptoms associated with neonatal infection. Most patients have typical symptoms of early-onset neonatal sepsis, including nonspecific lethargy, fever, and poor feeding; manifestations of sepsis may include septic arthritis and osteomyelitis. In a few patients the disease presents after the first week of life. Meningitis may occur with either early-onset or late-onset disease. Brain abscesses associated with subtle clinical abnormalities rarely develop for weeks to months before presentation.¹⁴ *Proteus* brain abscesses are associated with a high degree of mortality, frequent complications, and increased risks of neurologic deficits in survivors.^{18,31,39,64} Hydrocephalus is a particularly frequent complication and should be anticipated. Destruction of the brain may progress to porencephaly or compartmentalization of ventricles and often requires surgical intervention.³¹ Computed tomography is useful, especially in diagnosing and following progression of cerebral complications.⁶⁴

Urinary tract infection with these bacteria involves predominantly younger patients and often is associated with elevated urinary pH; clinical findings and urine abnormalities often are less striking than in patients with *E. coli* urinary tract infections.³⁴ Thirty percent of patients may show recurrent infection during the 12 months after receiving initial treatment.³⁴ Indwelling urinary catheters increase the risk for *Proteus* colonization and infection. Long-term indwelling urinary catheters or stents may become blocked by encrustations of aggregated struvite

crystals; prolonged colonization with urease-producing *P. mirabilis* is associated with this complication.³⁸ *P. mirabilis* is the most common pathogen associated with xanthogranulomatous pyelonephritis,³ which can mimic Wilms tumor and usually is not seen in childhood except in malnourished patients.

Proteus spp. often are implicated as agents of septicemia in adult patients and account for approximately 8% of gram-negative bacteremias in this group.^{21,36} In 60% of *Proteus* bacteremic episodes in adults, the urinary tract has been determined to be the source²¹; no anatomic source is identified in 20% of cases of *Proteus* bacteremia. *P. mirabilis* and *P. vulgaris* are the species responsible for most cases of *Proteus* bacteremia. The overall incidence of gram-negative enteric bacteremia in pediatric patients is lower than that of adults; 5% of such cases are caused by *Proteus* spp.²¹ As in adults, the genitourinary tract is the source identified most frequently.²¹ Predictors of bacteremia in adults with *Proteus* urinary tract infection are community acquisition, hydronephrosis, bacteremia greater than 10%, a C-reactive protein value greater than 10 mg/dL, and hypothermia or hyperthermia at diagnosis.¹⁵ Mortality rates average less than 40% and strongly depend on the severity of underlying disease in the host.^{21,36}

Osteomyelitis,^{32,52,69} pneumonia,^{21,36,54} mastoiditis,⁴⁴ and wound infections³⁶ also occur. Rarely, native-valve endocarditis has been caused by *P. mirabilis*.¹⁷ Severe multifocal osteomyelitis requiring bilateral above-knee amputation for cure has been reported in a patient with human immunodeficiency virus infection despite a reasonably good CD4⁺ cell count.⁵¹ *Proteus* spp. have been isolated commonly from chronic suppurative otitis media on several different continents.^{25,72} Reports that *Proteus* spp. are major pathogens of otogenic brain abscess in pediatric and adult patients support this association.^{26,53} Pediatric osteomyelitis secondary to contiguous infection of traumatized soft tissue often is polymicrobial, and *Proteus* spp. have been implicated as co-pathogens in at least 10% of such cases.⁵² Sickle cell anemia is a risk factor.^{2,32}

DIAGNOSIS

Proteus is suspected readily because of its ability to swarm on the surface of moist agar. A selective medium developed for the isolation of *Proteus* organisms relies on the ability of all members to produce a dark brown pigment in medium containing DL-tryptophan.²⁷ Production of urease, lack of indole production from tryptophan, and a positive result with ornithine decarboxylase testing distinguish *P. mirabilis* from *Providencia* spp. and other *Proteus* spp.³⁷

TREATMENT

Treatment of meningitis caused by *Proteus* spp. should conform to standard regimens recommended for gram-negative meningitis. *P. mirabilis* usually is sensitive to ampicillin, however, and this drug alone or combined with an aminoglycoside often is suitable therapy when the identity and susceptibilities of the infecting organism are known.⁶⁰ A third-generation cephalosporin often is an alternative, but resistant extended-spectrum β -lactamase-producing strains and β -lactamase inhibitor-resistant strains have been described in pediatric patients.^{19,40} Consecutive lumbar punctures should be performed for *Proteus*

meningitis until cerebrospinal fluid cultures are sterile. A minimum of 2 weeks of antibiotic therapy is recommended after bacteriologic cure has been achieved. Ventricular aspiration or drainage of abscesses may be required to direct therapy, based on persistence of organisms at these sites. Open drainage of abscesses often is necessary, but resolution of abscess formation with the use of antibiotic therapy alone has been reported.⁶⁵ Intraventricular antibiotics are not of proven benefit in terms of mortality or morbidity but have been used to clear ventricular colonization. A 15-year-old boy with *Proteus* mastoiditis and meningitis was treated successfully with intravenous trimethoprim-sulfamethoxazole.⁴⁴

Effective treatment of local infections or septicemia relies on appropriate choice of antibiotics, often including an aminoglycoside, combined with surgical debridement and drainage of abscesses as necessary. Many experts recommended “double coverage”—a cell wall-active agent plus an aminoglycoside—especially when the infection is severe or is caused by an indole-positive strain. In a large, three-continent longitudinal survey, approximately 5% of *P. mirabilis* strains exhibited phenotypic extended-spectrum β -lactamase resistance patterns.²² In France, 59% of 1008 urinary *P. mirabilis* isolates were resistant to amoxicillin, 48% were resistant to piperacillin, 34% were resistant to amoxicillin-clavulanate, and 2.8% were resistant to piperacillin-tazobactam.⁴¹ One third of isolates were resistant to trimethoprim-sulfamethoxazole.⁴¹ In Japan, extended-spectrum β -lactamase production in *P. mirabilis* went up from 7% in 2000 to 12.9% in 2009.⁴⁸ Over a 10-year period in Taiwan, susceptibility to cefotaxime decreased from 93% to 82%; to ceftazidime from 100% to 95%; to ciprofloxacin from 80% to 54%; about 8% were extended-spectrum β -lactamase producers.⁷¹ A report from China details the combination of carbapenem resistance and quinolone resistance in 19 isolates; all of them had the *Klebsiella pneumoniae* carbapenemase-2 gene.²⁹ Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.⁴⁶ In one study, amikacin retained better activity than did other aminoglycosides.⁴¹ In France, 65% of all colistin-resistant gram-negative isolates were *Proteus* species.¹ Most *P. mirabilis* urinary tract infections respond to ampicillin, but some organisms have been shown to acquire a plasmid-mediated β -lactamase.⁴² Failure to clear bacteria should alert the physician to the possibility of urolithiasis or structural abnormality; removal of stones or surgical correction of anatomic defects often is required for cure.

The genus *Providencia* comprises pathogens most commonly associated with urinary tract infection. *Providencia* spp. are encountered most often as pathogens in hospitals or long-term care facilities and can be responsible for outbreaks of multidrug-resistant infection.⁴⁴

BACTERIOLOGY

Providencia spp. (named after the city of Providence, Rhode Island) are motile gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine.^{9,33} The genus distinguishes “urease-negative” organisms, *P. rettgeri*, *P. stuartii*, *P. alcalifaciens*, *P. rustigianii*, and *P. heimbachae*, from the otherwise biochemically similar “urease-positive” *Proteus* spp.^{16,33} Urease is produced by most strains of *P. rettgeri* and by 15% or less of *P. stuartii* strains.²⁸ *Providencia* spp. also differ from other Proteae in their ability to produce acid from inositol. Strains are differentiated further by reactivity with straight-chain hydroxy alcohols.³³ For a detailed discussion of taxonomy and characterization of *Providencia* spp., the reader is referred to the review by O’Hara and colleagues.²⁹

EPIDEMIOLOGY

Providencia organisms are recovered uncommonly from stool in healthy humans, but they frequently colonize indwelling or condom urinary catheters, particularly in patients receiving antibiotic therapy.^{5,6,11,17,44,45} In a Japanese study of patients with traveler’s diarrhea, *Providencia* spp. were recovered, using a new selective medium, from 23 of 130 specimens tested.⁴⁶ *P. alcalifaciens* has also been associated with a foodborne outbreak of gastrointestinal disease with seven primary and four secondary cases.³⁶ A study of retail meats in Thailand found *Providencia* strains in 68% of chicken, 68% of pork, and 72% of beef sampled; *P. alcalifaciens* was the most common organism identified.³⁷ *Providencia* spp. have been recognized as pathogens for more than 50 years⁸; *P. rettgeri* and *P. stuartii* are the most common species implicated in urinary tract infection.^{11,13,14,25,45} Multiple biotypes of *P. stuartii* have been identified in hospital outbreaks, indicating the probability of multiple sources of colonization.¹ Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analysis of outbreaks.³⁵

PATHOPHYSIOLOGY

P. stuartii does not seem to have greater access to the urinary tract compared with other bacteria; in patients with long-term catheters, the incidence of bacteriuria caused by this organism is equivalent to that caused by other uropathogens.⁴⁴ Rather, *P. stuartii* manifests an extraordinary ability to persist within the catheterized urinary tract.⁴⁵ Bacteriuria may take weeks to months to clear. A mannose-resistant, *Klebsiella*-like hemagglutinin may play an important role in the persistence and adherence of *P. stuartii* to urinary tract catheters.²⁷

Despite the similarities between *P. mirabilis* (the major pathogen responsible for urolithiasis in children)⁴ and urease-producing *Providencia* spp., the latter organisms rarely are associated with formation of stones. *P. stuartii* occasionally produces urease with a higher affinity for substrate, but *P. mirabilis* ureases hydrolyze urea 6 to 25 times faster.¹⁵ Restriction-enzyme analysis of genes coding for the respective enzymes shows significant divergence.¹⁵ These differences may explain the more frequent association of *P. mirabilis* with formation of stones.

Some strains of *P. alcalifaciens* have been isolated more commonly in children with diarrhea, and enteropathogenicity has been shown in HEp-2 cells and a rabbit model.^{1,2} In vitro, *P. alcalifaciens* prefers

basolateral to apical entry into Caco-2 cells; they are taken up by endocytosis and appear to require an invasion.²⁴ Ex vivo *P. alcalifaciens* strains show the ability to translocate and to resist complement-mediated lysis.⁴³ In children with diarrhea, *P. alcalifaciens* often is associated with other enteric pathogens, so its role in pathogenesis remains unclear.³

CLINICAL MANIFESTATIONS

Although *Escherichia coli* and *Proteus* spp. account for most urinary tract infections in children, *Providencia* spp. have been reported as a cause of infection in children with spinal injury and long-term urinary tract catheterization.^{18,25} Most infections have been described, however, in elderly patients or adults with spinal injury who require long-term urinary tract catheterization.⁴⁴ Clinical findings are typical of those associated with urinary tract infection. Bacteremia is uncommon but devastating.¹⁹ In a study of 132 cases of bacteremia caused by members of the tribe Proteae, only eight were caused by *Providencia* spp., but four of those patients died of the infection.¹⁹ A single case of endocarditis and a case of relapsing pericarditis both caused by *P. stuartii* have been reported.^{20,39} In a newer case series of *Providencia* bacteremia, 11 of 14 cases were nosocomial, nine were polymicrobial, and the mortality rate was 29%; patients were a median age of 64.5 years, and cerebrovascular/neurologic disorders were the most common underlying illnesses.⁶

Eye infections caused by *P. rettgeri*, including conjunctivitis, dacryocystitis, keratitis, and endophthalmitis, have been reported. These infections generally occurred in patients with compromise in ocular surface or in immunity.³¹

Providencia spp. have been implicated in the so-called purple urine bag syndrome, in which an enzyme from the organism causes 3-indoxyl sulfate to be formed, which discolors the urine blue or blue-violet. This syndrome usually occurs in patients with indwelling cystostomy or nephrostomy tubes.^{21,42} Xanthogranulomatous pyelonephritis with a nephrocutaneous fistula has also been reported.²²

Although central nervous system infection with *Providencia* spp. is extremely rare, meningitis occurred after a neurosurgical procedure in a patient in Turkey⁴⁰ and a left frontal lobe cystic mass was reported that was originally thought to be a tumor but proved to be a brain abscess caused by *P. stuartii*.²⁹

DIAGNOSIS

Infection with *Providencia* spp. should be suspected when indole-positive, urease-negative, gram-negative rods, which oxidatively deaminate tryptophan, are isolated in culture. Because patients with long-term catheterization may be colonized with multiple organisms, *Providencia* spp. frequently are overlooked or misidentified.⁸ Clinical laboratories should be encouraged to identify all bacterial colonies in patients with long-term catheterization in whom infection is suspected. Identification is particularly important because of the marked differences in susceptibility of uropathogens.³⁴

TREATMENT

Empirical therapy should be guided by antimicrobial susceptibility testing of the patient’s isolate and knowledge of susceptibilities of previously identified *Providencia* within the care facility. Removal of urinary tract catheters speeds eradication of these pathogens. Strains of *P. stuartii* and *P. rettgeri* commonly are resistant to many antibiotics. In a longitudinal Italian study of 223 *P. stuartii* isolates, 116 (52%) were extended-spectrum β -lactamase positive.⁴¹ The rate of extended-spectrum β -lactamase-positive isolates increased from 31% in 1999 to 62% in

2002.³³ Since the 1970s, multidrug resistance has emerged^{32,38}; many strains are resistant to sulfonamides, trimethoprim, nitrofurantoin, nalidixic acid, penicillins, cephalosporins, and aminoglycosides; some singular strains are resistant to most antibiotics in common use.³⁴ Imipenem-resistant strains have now been described.³⁸ One case report describes an isolate that carried *blaPER-1*, *blaVIM-2*, and *armA* (a 16S methylase gene that confers resistance to aminoglycosides).²³ Much of the observed resistance seems to be plasmid based¹²; quinolones and aztreonam have shown some promise in the treatment of such cases.^{7,10} One isolate in Israel was found to be carrying 27 different antibiotic resistance genes, most of them located on mobile genetic elements.³⁰ Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.²⁶ Organisms that are resistant to gentamicin and tobramycin may remain susceptible to amikacin.

Acknowledgments

I thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

Shigella

109

Theresa J. Ochoa • Margaret Kosek

HISTORICAL BACKGROUND

The term *dysentery* classically has been used to describe the frequent, painful passage of stools containing blood and mucus. The syndrome has been recognized since the time of Hippocrates. The differentiation of dysentery into bacillary and amebic forms followed the recognition by Shiga in 1898 that one form of dysentery was associated with a bacterium in the stools of affected individuals; their sera also were found to agglutinate the bacillus. In recognition of Shiga's achievement, the genus was eventually named after him. *Shigella flexneri* was first described in 1900, and only 14 years later shigellae became the main diarrheal agent in World War I.³⁰

The most important subsequent advance has been the recognition of the molecular basis of *Shigella* virulence. In the 1960s, researchers showed that shigellae invade the corneal epithelium of guinea pigs and cause keratoconjunctivitis (Sereny test). Subsequently, Formal and colleagues³⁶ showed that *Shigella flexneri* invades the intestinal epithelium. Since 1980, Sansonetti and colleagues^{256–258} and other investigators²⁶¹ have identified multiple plasmid and chromosomal virulence genes.

BACTERIOLOGY

Shigellae are small, nonencapsulated gram-negative rods that are members of the Enterobacteriaceae. Shigellae do not ferment lactose, or do so slowly, and are nonmotile (they lack the H [flagellar] antigen). They lack urease and do not produce hydrogen sulfide on triple sugar iron media or gas during metabolism of carbohydrate.⁸⁸ The somatic antigen (or O antigen) side chains that determine serotype and serogroup are attached as multiple repeating units to the lipid A core and core oligosaccharides shared with other members of Enterobacteriaceae. Envelope or K antigens that are heat labile also have been described, although their clinical relevance is uncertain. *Shigella* and *Escherichia coli* are closely related. Enteroinvasive *E. coli* (EIEC) strains have remarkable phenotypic and genotypic similarity with *Shigella* species and are difficult to differentiate. The sequencing of multiple housekeeping genes indicates that *Shigella* has risen on several different occasions from several independent ancestors by acquisition of the transferable forms of ancestral virulence plasmids within the group of nonpathogenic *E. coli*.²⁸⁵

Serogroup Classification

The genus *Shigella* has four species or subgroups (A, B, C, and D) and 43 serotypes.⁶⁵ Subgroups A, B, C, and D have historically been treated as species: subgroup A is referred to as *S. dysenteriae*; subgroup B as *S. flexneri*; subgroup C as *S. boydii*; and subgroup D as *S. sonnei*. Subgroups and serotypes are differentiated from each other by their biochemical characteristics and antigenic properties. *Shigella dysenteriae* (subgroup A), mannitol nonfermenters, includes 15 serotypes having O antigens that do not cross react immunologically. *Shigella sonnei* (subgroup D), ornithine decarboxylase–positive, slow lactose fermenters, share the same lipopolysaccharide (1 serotype). *Shigella* strains that ferment mannitol (in contrast to *S. dysenteriae*) but do not decarboxylate ornithine or ferment lactose (in contrast to *S. sonnei*) are classified as serogroups B and C. Of these, the strains that express lipopolysaccharides that are related to each other immunologically are group B (*Shigella flexneri*), whereas the strains whose O antigens are unrelated to each other or to other shigellae are group C (*Shigella boydii*). *S. flexneri* has eight serotypes; serotypes 1 through 5 are subdivided into 11 subserotypes. Although the numbering scheme for group C (*S. boydii*) serotypes extends to serotype 20, there are only 19 serotypes because *S. boydii* 13 is now reclassified as *Escherichia albertii*, and has been removed from the scheme¹²² (Table 109.1).

EPIDEMIOLOGY

Based on the findings of the Child Health Epidemiology Reference Group (CHERG) of the World Health Organization (WHO), it is estimated that globally 89 million community cases and 37 million outpatient cases of shigellosis occur annually in children younger than age 5 years.¹⁵⁷ Most of these cases occur in developing countries. In 1999, a review of the literature for 1966 through 1997 suggested that around 1.1 million persons die annually of shigellosis, including around 880,000 in Asia.¹⁴⁹ A review of the literature from 1990 through 2009 indicates that around 125 million shigellosis cases occur annually in Asia, of which, 14,000 are fatal.³¹ A systematic review of global causes of diarrheal disease mortality in children of articles published between 1990 and 2011, estimated 28,000 deaths due to shigellosis in children under 5 years in the world.¹⁵⁶ This estimate is much lower than a previous

TABLE 109.1 Classification of *Shigella* Subgroups

Serogroup	Species	Number of Serotypes
A	<i>dysenteriae</i>	15
B	<i>flexneri</i>	8 ^a
C	<i>boydii</i>	19 ^b
D	<i>sonnei</i>	1

^aGroup B serotypes 1–5 are subdivided into 11 groups.

^bAlthough the numbering scheme for group C serotypes extends to serotype 20, there are only 19 serotypes.

estimate of approximately 600,000 deaths due to shigellosis published by Kotloff et al. in 1999¹⁴⁹; and is compatible with the Asian estimate of 14,000.³¹ The lower estimates of deaths are associated with markedly reduced case-fatality rates rather than fewer cases.

Generally, *Shigella* spp. are associated with 5% to 10% of all diarrhea cases and 30% of dysentery cases, although estimates based on PCR-based diagnostics are higher.²⁰⁵ Dysentery associated with *Shigella* spp. is often severe and with longer duration.²³¹ Although epidemic *Shigella* dysentery is the most dramatic manifestation of *Shigella* infections in developing countries, most infections are caused by endemic shigellosis. Despite the fact that severe dehydration usually is not seen in shigellosis, shigellosis is disproportionately represented in severe and fatal cases of diarrhea, particularly in children younger than 5 years old. The incidence of *Shigella* is increased by undernutrition, particularly wasting,¹⁴⁶ and *Shigella* is one of the enteric infections that has shown to be most strongly correlated with linear growth deficits following infection.^{44,161} *Shigella* is a common cause of prolonged and persistent episodes of diarrhea, and the dominant cause of the clinical dysentery syndrome in populations living in poverty or exposed to conditions where hygiene and water quality are suboptimal. Therefore, the empirical management of dysentery should always include an antibiotic that has been demonstrated to have low levels of resistance as defined by the best available regional data on antimicrobial resistance.

According to surveillance reports of the Centers for Disease Control and Prevention, 10,000 to 15,000 cases of shigellosis have been documented each year during the past 30 years in the United States,⁶³ and it is currently estimated that nearly 500,000 cases occur annually in the United States, one fourth of which are domestically acquired; with 40 annual deaths.^{66,262} *Shigella* is the third most important Foodborne Diseases Active Surveillance Network pathogen in 10 sentinel states in the United States, with a population-based incidence of 5.7 per 100,000 population. The groups with the highest incidence are children younger than 5 years, black race, and Hispanic ethnicity.⁶⁶ However, incidence rates have decreased significantly in 2014 when compared with rates documented in 1996 and 1998 (46% decrease).^{64,66} Around 10% to 18% of persons with culture-confirmed *Shigella* infection in the United States are hospitalized.²⁰⁹

Because shigellae are spread through a fecal-oral route, they are especially prevalent where hygiene is poor. The organisms can be cultured from around toilets in homes where shigellae have caused disease. Shigellae are transmitted easily from person to person because the inoculum size required to cause disease is only 10 organisms in the case of *S. dysenteriae* serotype 1⁸⁵ and a few hundred organisms in the cases of *S. sonnei* and *S. flexneri*.⁸³ Hand washing and wearing gloves are mandatory procedures for individuals caring for patients with bacillary dysentery. Patients who lack the acid barrier provided by a normally functioning stomach because of prior gastrectomy or use of antacids are at increased risk for acquiring infection.

Epidemics usually are associated with exposure to contaminated water or food, although as might be predicted from the inoculum size, outbreaks related to swimming also occur.¹⁷⁷ Houseflies can be mechanical vectors of shigellosis, particularly where the fly population is large. A study in Bangladesh demonstrated that housefly population density correlates with shigellosis among children.⁸⁹ *Shigella* infection shows seasonal variation. In North America, few cases occur in the winter,

whereas in tropical regions, the peak is during the rainy season. Shigellae are worldwide and thrive where susceptible individuals are grouped together (including institutions for retarded or mentally ill individuals, prisoner-of-war camps, Indian reservations, the military, daycare centers, and the developing world).^{138,229,275} The devastating impact of *S. dysenteriae* type 1 epidemics in vulnerable concentrated populations is still notable as can be seen in refugee camps in Goma and Tanzania in the 1990s where attack rates ranged from 6.3% to 39.1% and case-fatality rates were estimated to be as high as 9% at some camps.^{101,137}

The species of *Shigella* causing most infections varies according to region. In developed countries, *S. sonnei* is the most common species, followed by *S. flexneri* (approximately 86% *S. sonnei* and 12% *S. flexneri*); however, in the developing world, this pattern is reversed, with *S. flexneri* being more common than *S. sonnei* (66% vs. 24%).^{66,143,175} In recent years, *S. sonnei*, which has historically been more commonly isolated in developed countries, is undergoing an expansion across industrializing regions in Asia, Latin America, and the Middle East. *Plesiomonas shigelloides* is hypothesized to protect populations with poor water supplies against *S. sonnei*. Improving the quality of drinking water supplies would, therefore, result in a reduction in *P. shigelloides* exposure and a subsequent reduction in environmental immunization against *S. sonnei*. This phenomenon would explain why *S. sonnei* is more common in industrialized countries.²⁸⁰

S. dysenteriae serotype 1 occurs primarily in Africa, India, and Bangladesh. *S. boydii* is found primarily on the Indian subcontinent.²⁰⁵ However, *Shigella* has shown temporal procession in serogroup dominance. Recently, epidemiologic transition has favored the emergence of *S. sonnei* as the dominant serogroup in some countries (i.e., Israel, Argentina, Vietnam), although the reason for this is not clear.¹⁴⁵ A large molecular epidemiology investigation in China has provided convincing evidence for numerous serotype switching events, as well as changing antibiotic resistance, of an emergent sequence type that has replaced *S. flexneri* 2a as the dominant serotype.²⁹⁵

Based on a study in South Africa, systemic shigellosis is associated with HIV-infected patients, primarily in older girls and women, potentially due to the burden of caring for sick children in the home. Death rates are higher in HIV-infected versus uninfected individuals.¹³⁶

Humans and other primates can be infected with shigellae, and an age-related risk for acquiring symptomatic shigellosis exists. In contrast to *Salmonella* spp., which causes disease most frequently in the first few months of life, shigellae infrequently cause illness in the first 6 months of life. The peak incidence occurs in children between 1 and 4 years of age, with fewer cases occurring in children aged 5 to 9 years old. Adults are at lower risk.

PATHOGENESIS

Invasiveness and Toxin Production

Shigella invades the colonic epithelium where it elicits an intense inflammation leading to tissular destruction. The main steps of colonic infection by *Shigella* are adhesion, invasion, intracellular replication, and cell-to-cell spread. The ability to invade mammalian cells is the most important virulence trait of *Shigella* spp.^{2,14,99,154,166,201,213,263} Uptake by M cells overlying Peyer patches with ingestion by macrophages under the M cells induces production of cytokines and recruitment of polymorphonuclear leukocytes (Fig. 109.1). Apoptosis is induced in macrophages after ingestion of shigellae; these events are accompanied by release of interleukin (IL)-1, IL-1 β , and IL-18, which triggers other inflammatory events.^{259,302,304} *Shigella* induces a controlled inflammatory response which includes release of both inflammatory (IL6, IL8, IL1 β , TNF α and β) and anti-inflammatory cytokines (IL10, TGF β).¹⁸¹ Polymorphonuclear leukocytes enter the gut lumen by moving between epithelial cells. *Shigella* enters the intestinal epithelium via the basolateral surface of polarized enterocytes by delivering several effectors that subvert cell signaling pathways, which then direct bacterial internalization by the epithelial cells.¹⁴ After penetration of intestinal epithelial cells, shigellae are located in vacuoles derived from the cytoplasmic membrane of the mucosal cells. The bacteria lyse these vacuoles, move intracellularly, multiply, kill the epithelial cells, and infect adjacent cells.^{57,189} Cell death is followed by formation of ulcerations and microabscesses in the colon.

Current Opinion in Microbiology

FIG. 109.1 Cellular pathogenesis of *Shigella* spp. *Shigella* passes the epithelial cells barrier by transcytosis through M cells and encounters resident macrophages. The bacteria evade degradation in macrophages by inducing an apoptosis-like cell death, which is accompanied by proinflammatory signaling. Free bacteria invade the epithelial cells from the basolateral side, move into the cytoplasm by vectorial actin polymerization, and spread to adjacent cells. Proinflammatory signaling by macrophages and epithelial cells further activates the innate immune response and attracts polymorphonuclear leukocytes. (From Ashida H, Ogawa M, Kim M, et al. *Shigella* deploy multiple countermeasures against host innate immune responses. *Curr Opin Microbiol.* 2011;14:16–23.)

In contrast to *Salmonella* infection, *Shigella* infection rarely spreads beyond the lamina propria, so bacteremia and metastatic infections are uncommon.

The genetic basis of virulence has been studied extensively.^{215,219} Invasiveness is the result primarily of genes on a large virulence plasmid (200 kb), containing a mosaic of around 100 genes and insertion sequences.^{109,110,115,226–228,261,263} These genes encode a molecular apparatus called a type III secretion system (T3SS) that is capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.²¹⁹ More than 50 effector proteins of the T3SS have been identified and their virulence function and phenotype described.^{15,214,263} Recent structural and functional studies suggest that two different sets of effectors are involved in inducing actin cytoskeleton reorganization to promote entry of bacteria into epithelial cells and in modulating cell signaling pathways to dampen innate immune responses induced on infection, respectively. Effectors involved in entry are produced independently of the T3SS activity, whereas effectors involved in controlling the cell responses are produced on activation of the T3SS.²²⁰ The invasive plasmid antigen (ipa) region includes genes for four polypeptides needed for invasion: *ipaA*, *ipaB*, *ipaC*, and *ipaD*. The proteins produced by these loci are recognized by the humoral immune system. IpaB function depends on the face of invasion; plays a role as a T3SS needle tip protein, as a pore-forming translocator protein, and as an effector protein.²³⁰ The product of the *ipaB* locus is essential for induction of apoptosis in macrophages.^{302,303} The IpaH protein family has E3 ubiquitin ligase activity.²⁴⁵ *Shigella* modulates macrophage cell death by activating nucleotide-binding oligomerization domain–like receptor (NLR) inflammasome to secure its own dissemination via IpaH7.8. This allows bacteria to escape from macrophages and spread to neighboring cells.²⁷⁷ The *mxi-spa* region of the virulence plasmid is necessary for orientation of the ipa-encoded proteins into the outer membrane of the bacteria. The *virG* gene encodes a protein that causes intracellular and intercellular spread of shigellae after invasion of epithelial cells. The *virF* gene regulates a locus (*virB*) that is responsible for positive regulation of the ipa genes.²⁴⁹

Chromosomal loci regulate expression of the virulence plasmid.²¹⁸ The keratoconjunctivitis provocation (*kcpA*) gene is a positive regulator

of the *virG* virulence plasmid gene that determines ability to spread within and between cells. Lipopolysaccharides play a role in resistance to nonspecific host defense mechanisms that are encountered during invasion of tissue. The *Shigella* lipopolysaccharides induce the trafficking of Toll-like receptor 4, the dominant mediator of the innate immune response.⁵⁸ Smooth colonies express the complete complex of lipopolysaccharide O side chains required for full virulence—the ability to invade epithelial cells, to multiply within them, and to resist phagocytosis.^{103,216} Rough colonial variants that lack complete lipopolysaccharides do not penetrate epithelial cells efficiently and are avirulent.

Some strains of *Shigella* spp. produce toxins that injure mammalian cells. A chromosomal locus in *S. dysenteriae* serotype 1 encodes a protein synthesis-inhibiting exotoxin (Shiga toxin, Stx) that is a major virulence factor in this serotype (and in the enterohemorrhagic *E. coli* serotypes that have the same or closely related genes).^{34,268} In addition to being potent protein synthesis inhibitors, Stxs are also multifunctional proteins capable of activating multiple cell stress signaling pathways, which may result in apoptosis, autophagy, or activation of the innate immune response.¹⁶⁰ This toxin is composed of a single copy of an A subunit (32,000 Da) that is linked to five copies of B subunits (7790 Da).²¹¹ The B subunits bind to a glycolipid cell receptor, globotriaosylceramide, followed by internalization. The A subunit cleaves an adenine residue from the eukaryotic 28S ribosomal subunit. The resulting block in elongation factor 1-dependent binding of aminoacyl tRNA to the ribosome causes cell death through inhibition of protein synthesis.²¹¹ Shiga toxin previously was considered to be a neurotoxin because its administration to mice or rabbits caused paralysis and death^{51,62,119}; it now is thought to target primarily the vascular endothelium. It causes fluid accumulation in rabbit ileal loops^{91,139} that probably is related to reduced fluid uptake by damaged villus cells.

The severity of *S. dysenteriae* serotype 1 infection relative to other *Shigella* serotypes is thought to be caused by production of Shiga toxin. Enterohemorrhagic *E. coli* serotypes, such as *E. coli* O157:H7, produce an identical (Shiga toxin 1) or similar (Shiga toxin 2) toxin and, similar to *S. dysenteriae* serotype 1, cause bloody diarrhea and hemolytic-uremic syndrome. Recently, stx producing *S. sonnei* has been described to produce more severe disease than is typical of non-stx producing infections, and 71% of 56 cases reported in California derived from Mexico had

clinical dysentery.¹⁵⁵ Enteroinvasive *E. coli* serotypes do not produce these toxins.⁷²

Shigella spp. also produce two enterotoxins, ShET-1 and ShET-2.²⁸⁶ All *S. flexneri* 2a strains produce ShET-1, whereas only 3.3% of other *Shigella* serotypes and no enteroinvasive *E. coli* serotypes possess the gene for this toxin.²⁰⁶ ShET-2 is produced by all *Shigella* spp.²⁸⁶ Genes of an additional toxin, designated *Shigella* enterotoxin, or Sen, have been found in 75% of enteroinvasive *E. coli* serotypes and 83% of *Shigella* strains.²⁰⁰ These enterotoxins may contribute to the high-volume, watery diarrhea often seen in the initial stages of the disease.²⁵ Vaccine studies using a mutant with deletions of these toxin genes have shown that one or both enterotoxins play a role in human disease.¹⁴⁸

Immune Response

Serum IgG, IgM, and IgA responses occur to the lipopolysaccharide and invasion plasmid antigens of shigellae.²¹⁰ Secretory IgA, specific to both of these sets of antigens, occurs in human milk and feces.⁷³ Protection is thought to be serotype specific. The level of IgG antibodies to lipopolysaccharides present in an individual before infection occurs determines whether symptomatic shigellosis develops.⁷⁷ No clear proof currently exists about the role of antibodies to the invasion plasmid virulence proteins or to the toxins. Cell-mediated immunity against shigellae also may play a role in resolution of infection. Production of $\alpha\beta$ T cells and natural killer cells mediates interferon- γ production that may be essential to defense from *Shigella*.^{159,292} Antibody-dependent cellular cytotoxicity against shigellae has been shown.

During infection, shigellae use several effectors to direct various cellular signaling pathways and to modify the innate immune activation of the host.^{215,225} *Shigella* release bacterial components (lipopolysaccharide, LPS, and peptidoglycan -PGN) and T3SS components.^{16,17,15,191} These are recognized as pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) by recognition receptors, such as toll-like receptors (TLRs), nucleotide-binding oligomerization domain-like receptors (NLRs), AIM2-like receptors (ALRs), and RIG-like receptors; and trigger host immune response against bacterial infection. Upon recognition, a subset of NLRs (NLRP1, NLRP3, and NLRC4) and ALRs (AIM2) form inflammasomes, which are multi-protein signaling complexes composed of NLR/ALR, the adaptor protein ASC, and inflammatory caspase, such as caspase-1 (canonical inflammasomes) and caspase-11 (non-canonical inflammasomes). Inflammasome activation results in release of pro-inflammatory cytokines (IL-1 β and IL18) and induction of pyroptosis.¹³⁵ In addition, the remnants of the host cell membrane that result from the disruption of the phagocytic vacuolar membrane may also stimulate inflammatory responses.⁸⁴ As *Shigella* cells multiply within macrophages, the T3SS effector IpaB assembles an ion channel within cell membrane to allow for potassium influx, which is recognized by the NLRC4-inflammasome and triggers pyroptosis.²⁶⁵

All this causes activation of the nuclear factor κ B and other terminal kinase pathways, with IL-8 appearing as a major chemokine, mediating the inflammatory burst that is dominated by massive infiltration of the mucosa by polymorphonuclear leukocytes.²²⁵ The levels of cytokines tumor necrosis factor- α , IL-1 β , IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor in stool correlate with the severity of shigellosis. In contrast to other cytokines, interferon- γ and its receptor²³⁹ are depressed early and increase during recovery. Fecal concentrations of tumor necrosis factor- α , IL-1 β , IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor are significantly higher in patients with *S. dysenteriae* serotype 1 than in patients with *S. flexneri* infection.²⁴¹ Elevated tumor necrosis factor- α and IL-6 levels in stool and serum have been associated with complications during infection with *S. dysenteriae* serotype 1.⁸⁰ Infiltration of polymorphonuclear leukocytes and lymphocytes into the intestine is controlled by these cytokines. Epithelial cell production of IL-8 and a low ratio of IL-1RA to IL-1 are responsible for the severe inflammation.^{13,255} T lymphocytes with suppressor-cytotoxic and helper-inducer phenotypes are recruited into the epithelium and lamina propria during infection with *Shigella*, related partly to the induction of HLA-DR expression in the rectal mucosa.²⁴⁰ Peripheral blood lymphocytes of infected individuals respond to *Shigella* antigens in vitro with production of interferon- γ

and IL-10.^{215,254} The delivery of as yet uncharacterized T3SS-secreted proteins enables *Shigella* to suppress the transcription of genes that encode antimicrobial peptides, which promotes the advance of bacteria deeper into the crypts in the intestine.²⁷¹

Shigella spp. elicits an inflammatory response during multiplication within macrophages and epithelial cells. *Shigella* multiplication in macrophage cytoplasm induces cell death, which is achieved by two distinctive pathways: activation of caspase-1 by IpaB, MxiI, or MxiH of the T3SS, or caspase-11, and translocation of lipid A from the cytosol, which occurs independent of caspase-1 and Toll-like receptor 4 activities. Recent studies have characterized *Shigella*-induced macrophage cell death as pyroptosis or pyronecrosis, which is accompanied by severe inflammation.^{16,15,108,241} *Shigella* seems to prevent epithelial cell death until the bacteria have fully multiplied, because it prefers these cells as replicative niche, spread to neighboring cells, and evasion of immune cells. *Shigella* has several countermeasures that inhibit epithelial cell death: (i) prevention of mitochondrial damage, (ii) activation of cell survival signaling, and (iii) prevention of caspase activation.¹⁵

PATHOLOGY

The main morphologic changes of shigellosis (superficial ulcerations, focal hemorrhages, mucosal edema, erythema, and friability) occur in the colon where the organisms invade.^{125,269} The rectosigmoid and distal segments of the colon typically are involved more severely than is the proximal colon. The epithelial cell damage may cause development of a pseudomembrane composed of thick, fibropurulent exudate tightly adherent to the necrotic ulcerated colonic mucosa. Pseudopolypoidosis also has been reported.⁵³ On microscopic examination, damage to epithelial cells, ulcerations, goblet cell depletion, and intense polymorphonuclear and mononuclear infiltration with crypt abscesses are seen. Rectal mucosa shows increased numbers of CD8⁺ and $\gamma\delta$ ⁺ T cells.¹²⁴ Vessels in the lamina propria are congested or thrombosed. Perforation of the colon usually does not occur as part of the colitis.²⁹ Evidence of inflammation and proinflammatory cytokines persists for at least 1 month after clinical resolution.²³⁸ Histologic changes generally are more severe and persistent¹⁰⁵ with *S. dysenteriae* than with *S. flexneri*.¹⁰

CLINICAL MANIFESTATIONS

The incubation period ranges from 12 hours to a few days (if a low number of organisms are ingested). Onset of high fever, toxicity, and crampy abdominal pain is sudden and typically precedes the onset of diarrhea. During the first 48 hours, high-volume watery diarrhea may occur (small bowel phase of disease); subsequently, low-volume, bloody, and mucous diarrhea develops in association with urgency and tenesmus (large bowel or "dysenteric" disease). In some cases, the watery diarrhea persists for several days without subsequent development of dysentery. *Shigella* is the predominant cause of dysentery in the world, and the appropriate management of dysentery is directed primarily at the appropriate antimicrobial coverage as described by regional surveillance.

Physical examination shows fever, signs of toxicity, tenderness over the lower abdominal quadrants, and hyperactive bowel sounds. Signs of dehydration may be present. Rectal examination reveals severe tenderness. Rectal prolapse may be present, particularly when diarrhea is associated with malnutrition.

The course without therapy typically lasts 5 to 7 days. Although it is true that many enteric infections exacerbate undernutrition, initiating a "viscous cycle" of diarrhea and undernutrition, *Shigella* infections are particularly likely to do so. *Shigella* incidence is increased in underweight children.¹⁴⁶ *Shigella* causes a severe protein-losing enteropathy⁴⁵ (which is lessened by early appropriate antibiotic therapy)⁴¹ and wasting of large amounts of vitamin A and zinc.^{61,193} Shigellosis is associated with prolonged and persistent illness and linear growth shortfalls in children.⁴⁴ Groups at risk for severe disease include young children, the elderly, and malnourished children (Box 109.1).

Children infected with *S. dysenteriae* type 1, when compared to children infected with other species, are more likely to have severe gastrointestinal manifestations: grossly bloody stools (78% vs. 33%),

BOX 109.1 Risk Factors for Severe Disease

Infants and adults >50 y
 Children who are not breastfed
 Children recovering from measles
 Patients with HIV
 Malnourished children and adults
 Any patient who develops dehydration, unconsciousness, hypothermia or hyperthermia, or has a history of convulsion with first seen

BOX 109.2 Complications of Shigellosis**Abdominal**

Persistent diarrhea
 Postdysenteric irritable bowel syndrome
 Ileus, toxic megacolon, intestinal perforation
 Protein-losing enteropathy, malnutrition
 Surgical complications: intestinal perforation and obstruction, appendicitis, intraabdominal abscesses

Neurologic

Seizures
 Headache, lethargy, disorientation, hallucinations
 Coma
 Severe toxin encephalopathy or ekiri syndrome

Bacteremia

In malnourished children, young infants, and HIV-AIDS patients

Hemolytic-Uremic Syndrome

Only with *Shigella dysenteriae* serotype 1

Urogenital

Vulvovaginitis, urinary tract infections

Other

Conjunctivitis, keratitis, corneal ulcers
 Reactive arthritis
 Reiter syndrome
 Hepatitis
 Myocarditis

more stools in the 24 hours before admission (median 25 vs. 11), rectal prolapse (52% vs. 15%), and extraintestinal manifestations: leukemoid reaction (22% vs. 2%), hemolytic-uremic syndrome (8% vs. 1%), severe hyponatremia (58% vs. 26%) and neurologic abnormalities (24% vs. 16%).¹⁴³

The need for surgical intervention in shigellosis is rare but is associated with significant morbidity and mortality. In a series of 57 children with complications of shigellosis requiring surgical intervention,¹⁹² intestinal obstruction (53%), appendicitis (28%), and colonic perforation (17%) were the most common occurrences (Box 109.2).

Although the organism usually is excreted for only a few days or weeks (range, 1 to 30 days), carriage of the organism has been described.^{75,167} Asymptomatic or mildly symptomatic infection of infants and toddlers living in an endemic area occurs commonly and is usually transient, lasting no more than a few days.¹⁰⁶

Extraintestinal Manifestations and Complications

Multiple extraintestinal complications have been described with *Shigella* infection (see Box 109.2). Seizures have been reported in 10% to 45% of hospitalized children with culture-proven shigellosis.^{23,27,33,81,94} In outpatient settings, the frequency of seizures is very low. Children who

develop neurologic complaints may have lethargy, severe headache, disorientation, hallucinations, or self-limited convulsions lasting less than 15 minutes.^{21,24,27,197} Seizures are most likely to occur in very young patients, patients with a high peak body temperature, and patients with a family history of convulsive disorders.^{23,150} Seizures can be focal, although typically, they are generalized.

When symptoms related to the nervous system occur, they are likely to appear early in the illness, even preceding development of diarrhea. Death rarely has been described¹¹⁸; most children recover completely with no residual neurologic deficits.²⁴ In contrast, in Bangladesh, where seizures in shigellosis typically are associated with factors known to alter consciousness (e.g., hypoglycemia, hyponatremia, fever), mortality rates are high.¹⁴² Children with *Shigella* encephalopathy have significantly higher case-fatality rates than children with shigellosis without encephalopathy.⁶⁸ The pathogenesis of neurologic signs and symptoms during episodes of shigellosis is unclear. Hypoglycemia and electrolyte abnormalities are found in a few patients.²⁴ Direct invasion of the central nervous system during *Shigella* bacteremia is very rare.²⁹³ Simple febrile seizures might explain convulsions in a few children with dysentery, but some children who have seizures during episodes of shigellosis do not experience seizures during other febrile infections and are outside the age range usually associated with febrile seizures.²⁴ Shiga toxin formerly was thought to cause the neurologic symptoms because it was considered to be a neurotoxin; however, data now clearly show that Shiga toxin is not responsible.²² In an animal model of *Shigella*-related seizures, corticotropin-releasing hormone, a stress neurohormone, was associated with increased susceptibility to seizures after exposure to *S. dysenteriae*.²⁹⁸ Studies from the same group have demonstrated that proinflammatory mediators are involved in *Shigella*-related seizures²⁹⁷; however, these researchers found that prostaglandins, which are host mediators induced during the inflammatory process, are not involved in the enhanced seizure response after exposure to *Shigella*.²⁹⁹

Severe toxic encephalopathy has been described. This syndrome (ekiri), as originally described in Japan, was characterized by dysentery with hyperpyrexia, convulsions, sensory disturbances, and rapid progression to death.²⁵⁰ The children died of cerebral edema early in the course of disease (6 to 48 hours after onset). Mild hyponatremia has been a common finding.¹⁰² Children with ekiri did not have sepsis, disseminated intravascular coagulation, hemolytic-uremic syndrome, or severe dehydration. This toxic encephalopathy is rare. Whether this syndrome is part of a continuum of central nervous system dysfunctions with seizures and other encephalopathic symptoms or has a completely different pathogenesis is unclear.

Hemolytic-uremic syndrome (microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure) or isolated hemolysis has been reported, mainly after infections with *S. dysenteriae* serotype 1 and rarely after infection with *S. flexneri*.²³⁶ Vascular endothelial cell damage by Shiga toxin is considered to be the initial event, although endotoxin absorbed from the gut also may play a role.¹⁴⁷

Ileus that progresses to toxic megacolon with distended loops and eventual intestinal perforation occurs.²⁸ It is seen mainly with *S. dysenteriae* serotype 1 infection.

Septicemia in shigellosis is a rare occurrence except in human immunodeficiency virus (HIV)-infected patients, malnourished children, young infants, and children with *S. dysenteriae* serotype 1 infections.^{112,136,186,264} The mortality rate is at least twice as high in dysentery-associated sepsis as in shigellosis uncomplicated by bacteremia. The serogroup-related mortality risk in cases of *Shigella* bacteremia has been reported to be 85% for infection with *S. dysenteriae*, 43% for infection with *S. flexneri*, and 25% for infection with *S. sonnei*; bacteremia rarely is reported with *S. boydii* infection.¹⁸² In Bangladesh, *Shigella* bacteremia was found in 4% of patients.²⁷⁶ When bacteremia occurs with dysentery, it is as likely to be caused by other enteric bacteria as by the *Shigella* itself. The occurrence of *Klebsiella*, *E. coli*, and other enteric pathogens in blood cultures of children with shigellosis presumably reflects loss of the barrier function during severe colitis.²⁰² *Shigella* bacteremia may be complicated by disseminated intravascular coagulation and multiorgan failure. Bronchopneumonia may develop in septicemic children,⁵ but its pathogenesis is unclear. Children who die of shigellosis

often have pneumonia at autopsy.⁵³ HIV-infected patients with systemic shigellosis are more likely to die than patients not infected with HIV.¹³⁶

Other extraintestinal infections rarely are caused by *Shigella* spp. Vaginitis with a bloody discharge (sometimes lasting for months in the absence of specific therapy) may occur, usually without concurrent or recent diarrhea.^{78,199} *Shigella* cystitis, not always associated with diarrhea, has been described, usually in girls.³³ Conjunctivitis, keratitis, corneal ulcers, and iritis are other uncommon manifestations of shigellosis that usually are assumed to occur after autoinoculation.^{33,281} Hepatitis with mildly abnormal liver function test results has been described.²⁷⁴ Myocarditis manifested clinically by hypotension despite fluid replacement, arrhythmia, heart block, or low voltage on electrocardiography and pathologically by interstitial lymphocytic infiltrates and focal necrosis has been described.²⁴⁷

Postinfectious complications of shigellosis include reactive arthritis and postinfectious irritable bowel syndrome. Reactive arthritis may develop after infections with enteric pathogens such as *Shigella*, *Campylobacter*, *Salmonella*, or *Yersinia*.⁵⁹ However, the lack of a clear case definition precludes assessing the real disease burden of postinfectious arthritis. In general, reactive arthritis after shigellosis occurs especially in adults who are HLA-B27 positive; is uncommon in children⁵⁵; and is unlikely to be associated with *Shigella* vaccines in developing countries.⁹⁸ Postdysenteric irritable bowel syndrome occurs in some patients after recovery.²⁹¹ In a recent case-control study of children in Italy, 43% of children with prior *Shigella* infections were found to have symptoms of postinfectious irritable bowel syndrome versus 11% of controls.²⁶⁰ However, in a study conducted in the Netherlands the prevalence of postinfectious irritable bowel syndrome after *Campylobacter*, *Salmonella*, or *Shigella* infections was 9%.¹⁰⁷

Shigellosis in the Neonatal Period

Bacillary dysentery is rare in neonates.^{34,86,92,111,158} More than half of the reported neonatal cases occurred during the first 3 days of life, which is consistent with fecal-oral transmission during delivery,^{104,204} usually from a symptomatic mother. Although a neonate with shigellosis usually has only low-grade fever with diarrhea of variable severity,^{6,152,195} septicemia^{164,248} and chronic diarrhea are more common than in older children. Intestinal perforation has been reported in neonatal shigellosis.²⁷³ Diarrhea more often is nonbloody in infants; fever also occurs less commonly than in older children.¹²¹ Data on age-related mortality caused by shigellosis in developing countries suggest that the mortality rate of the neonate is more than twice that of older children.

Shigellosis in Acquired Immunodeficiency Syndrome

In patients with acquired immunodeficiency syndrome (AIDS), shigellosis not only is more common and more severe but also is associated more often with bacteremia.^{35,120,136} In contrast to the usual short, self-limited course of shigellosis, *Shigella* infection in patients with AIDS may be chronic and relapsing, despite appropriate antibiotic treatment.^{153,267}

LABORATORY FINDINGS

The fecal leukocyte examination is helpful in evaluating a patient with fever and watery diarrhea and in monitoring the response to antimicrobial therapy. Direct microscopic examination of fecal mucus stained with methylene blue reveals sheets of polymorphonuclear leukocytes in patients with colitis, including most patients with shigellosis.¹¹⁴ The blood leukocyte count in patients with shigellosis often is normal, although leukopenia or leukocytosis may occur.¹⁹ The differential of the blood leukocyte count typically shows an increased percentage of band forms. Approximately one-third of children with shigellosis have more bands than segmented neutrophils in their peripheral blood smear. A leukemoid reaction, with a peripheral leukocyte count greater than 50,000/mm³, has been reported, mainly with infections caused by *S. dysenteriae* serotype 1.⁵⁴ A leukemoid reaction has been reported in 10% of patients infected with the Shiga bacillus. When examination of cerebrospinal fluid is performed in children with neurologic symptoms, normal results usually are obtained, although some patients have a mild lymphocytic pleocytosis. Likewise, when electroencephalography is performed, the results usually are normal.²⁴

DIAGNOSIS

Bacillary dysentery usually is suspected in children who present with bloody diarrhea, high fever, tenesmus, and generalized toxicity. However, approximately half of children do not develop bloody diarrhea during the course of their disease. This fact is especially relevant in developed countries, where most infections are caused by *S. sonnei*. The presence of only watery diarrhea does not exclude the possibility of shigellosis, especially in an ill patient with high fever.

Isolation Techniques

Proof of the diagnosis of suspected bacillary dysentery often is problematic and no licensed rapid diagnostic tests currently exist for shigellosis. Definite diagnosis of *Shigella* infection routinely depends on isolation of the organism from stool specimens or rectal swabs. The bacteria may not survive in fecal specimens during transit, however, and special selective media are necessary for isolation. Recovery of shigellae is easier early in the course of the disease than later because the number of viable organisms in stools decreases significantly during late stages of the disease. Even in adult volunteer studies, when appropriate stool cultures were obtained daily, cultures failed to isolate shigellae in approximately 20% of volunteers who had ingested the organism and developed diarrhea.

Several measures increase the likelihood of isolating *Shigella*. Specimens should be processed without delay. Pre-enrichment broth does not significantly impact isolation rates, and the main determinant of success in isolating *Shigella* is rapid processing time (time between voiding and storage in an appropriate transport medium) and minimal time to primary plating. If a specimen cannot be processed immediately, a transport medium, preferably Cary-Blair, should be used. More than one stool culture or rectal swab should be obtained and inoculated promptly onto at least two different culture media, and rapid plating onto primary media is rewarded by increased rates of isolation. Specimens should be plated lightly onto MacConkey, xylose-lysine-deoxycholate, or Hektoen enteric agar, whereas heavier plating is necessary for the more inhibitory *Shigella-Salmonella* medium.^{196,279} After overnight incubation at 37°C, suspect colonies are transferred to triple sugar iron and lysine iron agar slants and incubated again overnight. Slants showing characteristic reactions of alkaline red slants, acid butt, and production of gas are tested biochemically for presumptive identification and then serologically for definitive identification.

Other Diagnostic Methods

Because presumptive identification of *Shigella* takes at least 48 hours and definite identification takes approximately 72 hours, attempts to develop rapid diagnostic methods are being made, especially because the early institution of treatment is important in shigellosis. PCR can detect as few as 10 colony-forming units of *S. flexneri* in stool specimens, whereas the sensitivities of DNA probe hybridization (with no amplification, often which are serotype specific) and standard biochemical methods are 10³ and 10⁶ colony-forming units, respectively and is the current gold standard diagnostic test in the research setting. Most PCR diagnostics rely on the detection of the *ipaH* gene, a multicopy element that is found on the chromosome and on the invasion plasmid of shigellae, has been developed and found to be more sensitive than the probes that were used previously, and is conserved across serogroups.²⁸⁸ Molecular-based diagnoses have revealed that the sensitivity of culture is quite low, and now have an important role in attributing an increased burden of moderate and severe diarrhea to shigellosis.¹⁷³ Recently in a subset of specimens from the Global Enterics Multisite Study (GEMS), the fraction of attributable disease in moderate to severe diarrhea was 9.6% based on culture, and 17.6% based on a detection threshold of 1.4 × 10⁴ ipaH copies.¹⁷³ The development of a broadly reactive point of care diagnostic test is a priority to improve care in settings where most cases of shigellosis occurs.

Serologic studies are not helpful in establishing the diagnosis of shigellosis in individual patients; humoral antibodies develop after clinical recovery. Serologic studies may be helpful, however, in epidemiologic studies to define the level of endemicity of shigellosis.

DIFFERENTIAL DIAGNOSIS

Colitis of any etiology manifesting as acute-onset bloody diarrhea with fever and abdominal cramps can mimic shigellosis. Etiologic agents to be considered include *Campylobacter* spp., *Salmonella* spp., *Clostridium difficile*, *Yersinia enterocolitica*, *Vibrio parahaemolyticus*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli* (e.g., serotype O157:H7), and *Entamoeba histolytica*. The initial presentation of inflammatory bowel disease can mimic shigellosis.

An etiologic diagnosis of acute colitis syndrome on the basis of clinical presentation is difficult to make, although some data suggest a specific causative agent. In developed countries, *Campylobacter* is the most common cause of acute infectious colitis. Shigellosis should be suspected when evidence exists of person-to-person spread and when convulsions or other neurologic symptoms develop. A history of previous antibiotic treatment suggests diarrhea related to *C. difficile*, and previous consumption of seafood suggests *V. parahaemolyticus*. *Yersinia* infections are found mainly in the cooler regions of Europe and North America; the disease may mimic acute appendicitis because of the right lower quadrant pain associated with mesenteric lymphadenitis.

Enterohemorrhagic *E. coli* (EHEC) or Shiga toxin producing *E. coli* (STEC) infection often causes bloody diarrhea with little or no fever, in contrast to shigellosis, in which high fever is typical. Negative stool cultures for the mentioned bacterial pathogens may suggest infection by enteroinvasive *E. coli*. Amebiasis causes a colitis similar to the colitis caused by *Shigella*,²⁷⁰ although it is of slower onset, with a lower degree of fever; the findings on fecal leukocyte examination are negative. The involvement of the colon with amebiasis is less diffuse than in shigellosis; areas of normal mucosa are found between ulcerations.

A prolonged course with negative cultures, especially with ancillary PCR-based diagnostics targeting the ipaH antigen, should raise concern about the possible presence of either ulcerative colitis or Crohn disease. When watery diarrhea is present, the list of possible etiologic agents is even longer, although many agents that cause watery diarrhea are associated with little or no fever and are not often confused with shigellosis. The diagnosis usually cannot be made by clinical presentation alone and requires laboratory confirmation.

TREATMENT

Fluid Administration

Dehydration is less a problem with shigellosis than with rotavirus or toxigenic *E. coli* infection. Some children with shigellosis, particularly young infants, have dehydration during the course of the disease. The high-volume watery diarrhea seen early in the course of the disease may cause excess losses of fluids and electrolytes; likewise, in patients with severe colitis, systemic toxicity and vomiting may cause anorexia that interferes with fluid intake.

Assessment of the hydration status of the patient on admission is mandatory, with early institution of appropriate fluid and electrolyte therapy needed. Low osmolality oral rehydration (total osmolality 245 mOsm/L, 75 mEq sodium, 20 mEq potassium, 10 mmol/L citrate, 75 mmol/L glucose), an improved choice especially in undernourished children, should be administered when available. Oral rehydration with commercially available solutions (e.g., Pedialyte) also is acceptable, and continued feeding is to be encouraged whenever possible. Administration of intravenous fluid therapy is necessary in children who are comatose, have an ileus, or are in shock. Early (12 to 24 hours after oral fluids are begun) breast-feeding and age-appropriate feeding in these children is a priority, especially in undernourished patients. Children with severe disease, seizures, and/or obtundation should have glucose and serum sodium levels monitored because hyponatremia and hypoglycemia are treatable complications seen in severe disease and possibilities to consider in severe cases or in patients who decompensate while receiving appropriate antibiotic therapy.

Antibiotic Therapy

Children who have dysentery and fever should be treated empirically with antimicrobial agents. WHO guidelines suggest that dysentery should be treated with antibiotics, the choice being decided by the antimicrobial

susceptibility pattern of locally circulating *Shigella* strains (WHO/CDR/95.3). If after 2 days of therapy, the patient's condition improves, a full course of therapy for 5 days should be given. If the patient does not improve, the antibiotic should be changed. If after the second antibiotic the patient does not show signs of improvement, the diagnosis must be reviewed, and stool microscopy, culture, and susceptibility testing should be performed where available.²⁰⁵

Appropriate antimicrobial therapy for shigellosis shortens the duration of fever and diarrhea, reduces the risk for developing complications,¹⁴ and shortens fecal carriage, thus attenuating transmission. Therapy should be stopped or changed on the basis of culture results (e.g., another pathogen or a resistant *Shigella* strain is isolated) and clinical response.

The choice of antimicrobial agent is complicated by the increasing frequency of antibiotic resistance.^{90,93,145,253} Organisms resistant to ampicillin, trimethoprim-sulfamethoxazole, tetracycline, and chloramphenicol have been reported from the Middle East,^{2,7,12,25,91,113,130,296} Africa,^{2,46,60,133,185,201} South America,^{170,200,207,234} Europe,^{34,67,127,131,151,169,180,289} Eurasia,^{29,217,300} Asia,^{3,8,43,140,169,171,173,178} and the South Pacific. Currently, none of these agents should be used for empirical therapy; they should be used only if the organism has been shown to be susceptible.¹⁸

Strains exhibiting resistance to one or several antimicrobials also are found commonly in some parts of the United States. Among 4021 *Shigella* strains evaluated by the National Antimicrobial Resistance Monitoring System between 2004 and 2013, 95.9% were resistant to one or more antimicrobial agents and 61% were resistant to two or more agents. Fifty three percent of strains were resistant to ampicillin and 43.5% to trimethoprim-sulfamethoxazole. Resistance to current first line antibiotics in the same series was 3.7% for azithromycin (data from 2011–13 only), 1.0% for ciprofloxacin, 3.0% for nalidixic acid, and 0.5% for ceftriaxone, so despite reports of clusters of cases with decreased sensitivity to azithromycin and ciprofloxacin in the United States, the best available evidence supports their continued use.^{48,49,116,266}

Multiresistant *Shigella* spp. are particularly likely to emerge in individuals who are exposed to multiple antibiotics²⁷⁸ (e.g., patients with AIDS) and individuals who recently have traveled to areas with known resistance (particularly India and Vietnam).^{79,144} Likewise, children in daycare centers are at risk for acquiring resistant organisms because the frequent use of antibiotics for otitis media may favor selection and emergence of resistant enteric organisms and because crowded living conditions and poor hygiene facilitate transmission.⁵⁰

Shigella has a long history of the rapid development of antimicrobial resistance. Generally, shigellae are susceptible in vitro to azithromycin, ceftriaxone, cefotaxime, cefixime, nalidixic acid, and quinolones. However, the rapid disseminations of resistance to these antibiotics is being reported in several regions, most notably Southeast Asia. Nalidixic acid-resistant *Shigella* has rapidly developed principally in Asia in particular, although it has also been well documented in Africa.^{70,105} Resistance to ciprofloxacin is increasingly common in India and in travelers returning from India.^{49,190,272} These fluoroquinolone-resistant strains have mutations in *gyrA* and *parC* and have developed efflux pumps.²²³ Similarly, azithromycin resistance is being increasingly reported. Resistance to ceftriaxone^{179,290} and extended spectrum beta lactamase producing (ESBL) made up 8.7% of isolates in a recent series.^{47,287}

In vitro susceptibility does not always predict clinical efficacy or superiority of one drug over another, however. The first-generation and second-generation cephalosporins are active in vitro but have been ineffective in clinical trials. Clinical studies have shown some drugs to be clearly superior to others when susceptibility data have suggested that either might work well.

Prevalent serotypes and resistance patterns can vary from year to year in a given locale. Typically, rates of resistance are related to the severity of disease caused by a given serotype. The more likely an organism is to cause severe disease, the more likely that resistant strains will emerge. *S. dysenteriae* serotype 1 is more likely to be multiply resistant than *S. flexneri*; *S. flexneri* is more likely to be resistant than *S. sonnei*. In Africa^{46,133} and Asia,^{37,39,71,178,198} *Shigella dysenteriae* resistance to nalidixic acid and ciprofloxacin has been reported. Nalidixic acid-resistant *S. flexneri* also have been recognized occasionally.⁷⁰ Local resistance patterns,

TABLE 109.2 Antibiotic Treatment of Shigellosis in Children

Antibiotic	Dosage ^a	Comments
Azithromycin	12 mg/kg/day once daily PO on day 1, followed by 6 mg/kg/day once daily on days 2–5 (maximum 500 mg/day)	Although published data in children are limited, its use is recommended by many experts Evidence of emerging resistance
Nalidixic acid	55 mg/kg/day PO divided every 6 h (maximum 2 g/day)	Not available in the United States; contraindicated in infants <3 mo Rates of resistance are rapidly increasing in Southeast Asia
Ciprofloxacin	15–30 mg/kg/day PO divided every 12 h (maximum 1.5 g/day)	Rates of resistance are increasing in Southeast Asia
Ceftriaxone	50 mg/kg/day IM or IV (maximum 2 g/day)	Current drug of choice for empirical therapy for severe dysentery in children ESBL strains are now well documented, particularly in India
Pivmecillinam	80 mg/kg/day divided 4 times a day	Limited geographic availability
Meropenem	120 mg/kg/day IV divided 3 times a day	Option for severe disease in patients with drug-resistant or suspected drug-resistant strains (from Southeast Asia)
Cefixime	8 mg/kg/day PO divided every 12–24 h (maximum 400 mg/day)	Not recommended as therapy in adults

^aRecommended duration of antibiotic therapy for shigellosis usually is 5 days.

IV, Intravenously; PO, orally.

history of travel to an area of frequent resistance,²⁷⁸ and severity of illness should determine antimicrobial selection.

Given the frequent occurrence of resistant organisms, optimal empirical therapy in children with dysentery should include azithromycin, a third-generation cephalosporin, nalidixic acid, or ciprofloxacin (Table 109.2).^{18,36,87,126,162,205,227} Although less well studied, ampicillin-sulbactam and pivmecillinam also have been shown to be effective in children. In children, oral cefixime seems to be superior to ampicillin-sulbactam.¹¹⁷ Adults do not respond well to usual doses of cefixime.²⁵²

In the absence of local susceptibility data, the WHO recommendations should be followed.^{282,294} First-line therapy is ciprofloxacin (in all age groups, including children), and second-line therapy is pivmecillinam (where available), ceftriaxone, or azithromycin. Azithromycin has the advantage of additionally being appropriate for use for campylobacteriosis, the second most common cause of dysentery. The use of quinolones in children has been controversial. An oral fluoroquinolone (ciprofloxacin, norfloxacin) seems to be optimal for adults.^{20,36,42,117,163,183,233} A considerable body of evidence from the long-term use of these drugs in children with cystic fibrosis has been accumulated, as has evidence from short-term use to treat typhoid fever and dysentery in children¹⁶²; no evidence of bone or joint toxicity or growth impairment has been found, except for transient musculoskeletal events (arthralgia) in some children.^{1,246} Nalidixic acid does not cause arthropathy or limit growth when it is used for a short time.²⁰⁸

Data for children suggest that norfloxacin at a dose of 10 to 15 mg/kg per day or ciprofloxacin at a dose of 10 mg/kg every 12 hours (maximum, 500 mg/dose) for 5 days is effective therapy.^{102,163,176,251} In adults, short-course therapy (1 or 2 days) with ciprofloxacin has been effective for treatment of infections caused by *Shigella* spp. other than *S. dysenteriae*, for which a 10-dose, 5-day regimen is superior.⁴⁰ Pediatric data suggest that even for *S. dysenteriae* serotype 1 a short course of ciprofloxacin 15 mg/kg per dose every 12 hours for 3 days is as effective as a 5-day course.³⁰¹

Because the patterns of antibiotic resistance of shigellae change, susceptibility testing should be performed on all clinical isolates if facilities are available, and the treatment should be changed accordingly. The recommended duration of antibiotic therapy for shigellosis usually is 5 days. Studies in adults and children have shown, however, that short-course treatment is nearly as effective as multiple doses in terms of symptomatic improvement,^{100,183} although eradication of the organism from stools is less likely to occur with a single-dose regimen.¹²⁸ Because a major goal of antibiotic therapy is to reduce person-to-person transmission, multiple doses are preferred.

After initiation of therapy, a resistant organism can be suspected in the event of persistence of fever, grossly bloody stools, or unchanged frequency of stools by day 3 of therapy.¹²³ Persistent presence of numerous fecal leukocytes (>50 per high-power field) and erythrocytes (>5 per high-power field) at day 5 also suggests resistance. These findings are important because morbidity and mortality rates are higher when the

organism is not susceptible to the initial drug of choice.¹²⁹ Protein-losing enteropathy is a more likely occurrence with resistant *Shigella* spp. if an inadequate agent has been used.⁴¹

Adjunctive Therapy

As with other forms of infectious colitis, ant motility agents should be avoided. Ant motility drugs, such as diphenoxylate (Lomotil), prolong the duration of fever, diarrhea, and excretion of the organism.⁸² It has been speculated that intestinal motility and the constant fluid flow are important host defense factors for clearing of the organism and recovery from the infection.

Nutritional therapy is a key in undernourished children living in poverty, where the burden of global *Shigella* infections is focused. A high-protein, high-calorie diet during convalescence is important, and children should receive at least one additional meal a day until pre-illness weight is achieved. Nutritional therapy based on green bananas, a food rich in amylase-resistant starches, has been shown to be more efficacious than diet therapy with rice- or yogurt-based therapies in different trials in Bangladesh and Venezuela.^{9,235} Because this is an affordable staple in many regions where shigellosis is endemic, its adjunctive use should be considered. Zinc should be given to all children at 20 mg/day (dosed as elemental zinc with sulfate and gluconate preparations being equally efficacious) for 10 to 14 days in children older than the age of 6 months; younger children should receive 10 mg/day for the same duration.

PROGNOSIS

Most patients recover eventually with or without specific antimicrobial therapy, although illness may be prolonged and severe if it is not treated with appropriate antibiotics.⁵² The mortality rate in developed countries is less than 1%, and life-threatening complications are rare events. With appropriate antibiotic therapy, defervescence usually occurs within 24 hours and the diarrhea decreases dramatically in 1 to 2 days. If left untreated, the disease usually lasts 1 week or more. In developing countries, childhood shigellosis is associated with significant morbidity and mortality (10% to 30%),³⁸ particularly if it is caused by *S. dysenteriae* serotype 1. Children with malnutrition are particularly likely to have a complicated course.⁶⁹ Shigellosis in malnourished children often causes a vicious cycle of further impaired nutrition, and repeated infections may be associated with impaired growth. Young infants and severely undernourished children are more likely to have bacteremia, which markedly increases mortality rates.²¹²

PREVENTION

In developed countries where person-to-person transmission of shigellae is the major mode of infection, personal hygiene measures are most important.¹⁴¹ Special attention to hygiene should be given in daycare centers, which sometimes play a central role in community-wide

outbreaks of shigellosis.¹⁹⁴ The close contact among children too young to control their excretions renders this setting ideal for fecal-oral spread of the organism. Children attending daycare centers frequently transmit infection to their families. Washing hands after defecating and before eating or preparing meals is important and helpful in preventing spread.¹⁴¹ Daycare personnel who prepare food should avoid performing diaper-changing duties. Sick children should be excluded from the daycare center or cohorted, and mothers should be educated regarding the possibility of being infected by their children and the use of the necessary precautions. Proper cooking of potentially infected food, appropriate refrigeration, and exclusion of individuals with diarrhea from handling food are important precautions. Education of staff members in proper hygiene is essential to infection control.²²⁸

Patients with diarrhea in institutional and hospital settings should be isolated for prevention of outbreaks. Aggressive investigation and early initiation of appropriate antibiotic therapy in cases of bacillary dysentery are important measures in reducing excretion of virulent shigellae and stopping spread of the disease. Use of antibiotics for prophylaxis is not recommended.

In developing countries, a safe water supply and appropriate sanitation systems are important measures for reducing the risk for shigellosis. Chlorination of drinking water is important. Water stored in vessels that permit hand dipping has been defined as a risk factor.²⁸⁴ Food prepared by street vendors also has been recognized as a risk factor. Prolonged breast-feeding is the best practical strategy for prevention of shigellosis (and most other enteric infections) in infants in most of the developing world.^{4,74,187} Educational efforts to promote breast-feeding in these areas are key to children's survival. Human milk contains specific secretory IgA antibodies against *Shigella* lipopolysaccharides and virulence plasmid-coded antigens.⁷³ Lactoferrin and other nonspecific (nonantibody) factors in human milk, the effect of human milk on the type of intestinal flora, and the supply of an uncontaminated food source all may contribute to the protective effect of breast-feeding against diarrheal disease.

Natural clinical *Shigella* infection confers approximately 75% protection against illness on subsequent exposure to the homologous *Shigella* serotype and in some instances against heterologous serotypes. Antibodies (serum or mucosal) directed against the lipopolysaccharide O-antigen appear to play a major role in protection. The first line of defense, however, occurs at the mucosa.²²¹ Serotype-specific (lipopolysaccharide-based) vaccines have been produced.^{95,96} Although early studies showed that immunization by the parenteral route with killed vaccines was ineffective, interest in this approach continues.^{26,76,165} Several oral, live organism-based *Shigella* vaccines have been studied. Avirulent mutants of *S. flexneri* that lack the ability to invade the intestinal mucosa are safe and effective in monkeys. Multiple doses of large numbers of organisms were required to protect humans, however. Attenuated vaccines prepared from streptomycin-dependent mutant strains were effective but unstable.¹⁸⁸ Genetically attenuated *S. flexneri* strains conferred protection but caused diarrhea when fed to some volunteers. Prototype-attenuated *S. flexneri* strains CVD 1208¹⁴⁸ and WRSS¹³⁴ have provided encouraging results in early clinical trials. Two nonliving vaccine approaches include the oral administration of proteosomes⁹⁷ and of inactivated *Shigella* bacteria.

A recent trial of a new set of O-specific polysaccharide conjugate vaccines in Israeli children has demonstrated immunogenicity; however, there was no significant level of protection for the *S. sonnei* conjugate in children 1 to 2 years old, the age when *Shigella* infections peak in most endemic regions. Additionally, the incidence rates at the study site did not allow for estimates of the efficacy of the *S. flexneri* conjugate.²²² New studies are being conducted using improved techniques for enhancing immunogenicity of the polysaccharide unit and using synthetic conjugates.^{226,244} Other new candidate vaccines are being evaluated, including the use of the major outer membrane proteins (OmpA) of *S. flexneri* 2a²³²; outer membrane vesicles (OMVs) from *S. flexneri*⁵⁶; invasive-complex-based vaccines (Invaplex) from *S. flexneri* 2a containing lipopolysaccharides^{243,283}; type III secretion system (TTSS) IpaB and IpaD proteins, which are more likely to be cross protective¹⁸⁴; and second-generation *virG* (*iscA*) *S. sonnei* live attenuated candidate vaccines.^{32,237}

No effective, licensed vaccine against shigellosis is available.^{132,145,165,168,172,221,224} Whatever prototype *Shigella* vaccines prove to be well tolerated, immunogenic, and protective, the final formulation will have to confer protection against multiple epidemiologically important serotypes to have a meaningful impact on the burden of shigellosis. Inclusion of multiple cross reactive *S. flexneri* serotypes to control the majority of the burden of endemic shigellosis in developing countries is the priority. The additional availability of a vaccine against *S. dysenteriae* 1 has the potential to severe and most lethal epidemics, but the relative decline of *S. dysenteriae* infections seen over the last 20 years is notable in most settings. *S. sonnei* is responsible for 5% to 15% of shigellosis in developing countries and is an important cause of traveler's shigellosis and of shigellosis in diarrhea in daycare centers in industrialized countries.¹⁶⁵ Given that there is only one serotype, that there is evidence that the relative burden of disease is increasing, and the recently noted presence of stx producing *S. sonnei*, the inclusion of *S. sonnei* appears to be increasingly advantageous. Clearly the rapid and progressive emergence of antimicrobial resistance that now includes all oral therapies available in the developing world argues strongly for increased investment in *Shigella* vaccines.

Serratia

Randall G. Fisher

Similar to other members of the Enterobacteriaceae, the genus *Serratia* contains species increasingly associated with opportunistic infection in the compromised host. One of the oldest bacterial organisms to be named,¹²⁴ *Serratia marcescens* is the chief species associated with disease in humans and has been associated with infection of the urinary tract, the respiratory tract, local wounds, and central venous catheters. Illness may be complicated by bacteremia and meningitis. Treatment of infection may be made exceptionally difficult because these organisms frequently are resistant to penicillins, cephalosporins, and aminoglycosides.

BACTERIOLOGY

S. marcescens can produce a red pigment resembling blood on contaminated foodstuffs. In the 6th century, the “miraculous” appearance of blood on food provoked superstition and scientific investigation. Troops were goaded into battle, and religious beliefs gained support because of the fortuitous growth of the saprophyte in bread.¹²⁴ In vitro, the red pigment produced by these strains (called “prodigiosin”) is toxic to cancer cells but not to nonmalignant cell lines.³⁴ In addition, prodigiosin has activity against the mitochondria of *Trypanosoma cruzi*,¹⁵ is larvicidal against *Aedes aegypti*,⁹⁵ and, together with serratolomide, is broadly antimicrobial, presumably allowing *S. marcescens* to compete with other microorganisms for limited nutrients.¹¹⁵

In 1819, *S. marcescens* was named by Bizio, who correctly interpreted the discoloration of cornmeal to be due to a living organism.⁷⁹ The genus name honors the Italian physicist Serrafino Serrati, who Bizio thought had been slighted in favor of Robert Fulton as inventor of the steamboat; the species name *marcescens* was drawn from the Latin word meaning “to decay.”

We now recognize the genus *Serratia* as comprising organisms that are straight, motile, catalase-positive, gram-negative rods. On solid agar, colonies are opaque; iridescent; and white, pink, or red. Organisms appear positive with the Voges-Proskauer test.⁵⁴ The genus may be distinguished from other Enterobacteriaceae by its use of caprylate or L-fucose as a sole carbon source and its hydrolysis of gelatin.^{54,119} Clinically relevant strains include *S. marcescens*, *S. liquefaciens*, *S. odorifera*, *S. ficaria*, and *S. plymuthica*.^{19,42} For a detailed review of the properties of *S. marcescens*, the reader is referred to the review by Hejazi and Falkner.⁵⁵

EPIDEMIOLOGY

S. marcescens was thought to be nonpathogenic in earlier times and was used as a biologic marker of transmission in 1906. In that year, N.H. Gordon, commissioned to study the atmospheric hygiene of the British House of Commons, gargled a liquid culture of *S. marcescens* and then quoted Shakespeare to an audience of agar plates in the otherwise empty House of Commons chamber.^{49,124} The organism subsequently was recovered from the plates, documenting the possibility of aerosol transmission of bacteria (Gordon reported no ill effects). The importance of *S. marcescens* as a biologic marker for hand-to-hand bacterial transmission, ascension of bacteria in the urinary tract in catheterized patients, and bacteremia after dental extraction is reviewed in detail by Yu.¹²⁴ Most remarkably, in investigations in 1950 and 1952 to judge the threat of biologic warfare to the United States, the US Navy released *S. marcescens* into the Pacific, where it became aerosolized and drifted 80 miles inland.¹³ Although an epidemic of *S. marcescens* infection in a San Francisco hospital coincided with this event, subsequent serotype and biotype analyses cast doubt on any relationship to the U.S. Navy experiments.³⁹ Rather the early San Francisco hospital experience heralded the increased frequency of nosocomial infections that would be observed in subsequent years.¹²⁴

In some studies, *S. marcescens* is the organism most frequently isolated from contact lens solutions and contact lens cases.^{96,126} Ex vivo mouse cornea studies show that the organism adheres to injured but not to intact corneas.⁹⁶ It is a cause of postoperative and posttraumatic endophthalmitis, with generally dire visual outcomes.¹¹³ All commercial multipurpose disinfectant solutions are active against the type strain but vary in their activity against actual clinical isolates. Polyquaternium-1–based solutions fared the worst in their activity against circulating strains.⁵⁸

Sporadic nosocomial outbreaks of infection were reported first in the 1950s and 1960s.^{75,97,122} Early outbreaks in a pediatric ward and neonatal nursery were attributed to contaminated intravenous solution and caps of bottles containing saline used to moisten umbilical cords.⁷⁵ As reviewed by Yu,¹²⁴ environmental sources before 1979 included disinfectants, water from ultrasonic nebulizers, respirators, arterial pressure monitors, and fiberoptic bronchoscopes. Environmental sources since have included suction traps,⁸⁴ intraaortic pressure transducers,^{10,120}

contaminated handwashing brushes,⁵ illicit intravenous drug paraphernalia,³⁰ contaminated urologic instruments,³⁷ colonized disinfectants or soaps,^{38,70,77} contaminated infant parenteral nutrition fluid,⁴³ contaminated whole blood or blood products,^{48,98} and inadequately sterilized breast milk pumps.⁵¹ In one report, a woman elected to discontinue breastfeeding when the breast pump tubing turned bright pink and was culture positive for *S. marcescens*.⁴⁰

Hand-to-hand transmission seems to be the primary mechanism of nosocomial spread. In one dramatic outbreak, spread of an organism with the same serotype, phage type, and antimicrobial sensitivity pattern was documented among four geographically separated teaching hospitals in the same region¹⁰³; spread likely was due to passive carriage of *S. marcescens* on the hands of rotating personnel. By 1979, it was apparent that nosocomial increase in *S. marcescens* infection was becoming a worldwide concern.¹⁹

Outbreaks in neonatal units and pediatric wards have been widespread, persistent, and associated with high morbidity and mortality rates.^{5,16,84,114} At the peak of one epidemic of invasive *S. marcescens* disease in a neonatal nursery, more than 90% of infants were colonized with the epidemic strain.³⁶ Increased rates of colonization have been associated with nearly 10-fold increases in rates of *S. marcescens* bacteremia and meningitis.¹²⁷ In a case-control study, neonates with *S. marcescens* bloodstream infection were at least three times more likely to have associated meningitis than were neonates whose blood cultures grew *Escherichia coli*.¹⁴ Outbreaks of multidrug-resistant strains have been especially troublesome in surgical subspecialty wards, and an outbreak has been reported in a bone marrow transplant unit.^{20,63} In the United States a multistate outbreak of *Serratia* infections was caused by contaminated prefilled saline and heparin syringes.²⁴

Biotyping may be successful in characterizing isolates, which can be traced in the hospital environment.^{53,111} Ribotyping or identification of a unique biochemical characteristic has proved useful for showing cross-contamination across hematology, gastroenterology, and neonatology units in a pediatric hospital.^{12,44} Use of typing methods may be particularly important because drug-resistant and drug-susceptible isolates of *Serratia* organisms may co-circulate.²⁸ Banding differences from pulsed-field gel electrophoresis of DNA digests are restricted in number from outbreak strains; increases in banding pattern may reflect genetic drift over time.⁷ Such DNA techniques have aided decisions regarding cohorting and closure of neonatal units and have been used to show cross-contamination of wards.^{57,82} DNA amplification techniques offer promise for characterizing isolates in future outbreaks and defining antimicrobial susceptibility.^{56,70,106}

PATHOPHYSIOLOGY

Pathologic findings of sepsis are similar to the findings of other gram-negative enteric bacilli. Postmortem examination of the lungs of patients with radiologic findings of *S. marcescens* pneumonia reveals a focal necrotizing pneumonia in most cases and hemorrhagic manifestations in some.⁹

Several properties may enhance virulence of *Serratia* organisms in human infection. The 56-kDa protease of *S. marcescens* seems to possess properties of a virulence factor. It enhances vascular permeability through activation of the Hageman factor–kallikrein–kinin pathway *in vivo*.⁷³ The protease also has the capacity to degrade host proteins important in humoral immune response, such as immunoglobulins and fibronectin,⁸³ and inactivates the chemotactic effect of C5a.⁹⁰ *Serratia* hemolysin indirectly may increase vascular permeability, local edema, and granulocyte accumulation.⁶⁴ Clinical strains seem to possess increased adherence properties compared with environmental isolates.⁸ Compared with some enteric organisms, *Serratia* organisms adhere better to epithelial cells of the bladder, which may facilitate development of urinary tract infection.³² Protease activity correlates with cytotoxicity in an *in vitro* model of eye infection; clinically strains from patients with keratitis have more protease activity than do those from patients with conjunctivitis.¹⁰⁹ Outer membrane vesicles (OMVs) are formed by *S. marcescens* in response to stress; OMVs likely play a role in virulence because it appears they function in toxin delivery.⁷⁶

Cell-mediated immunity and humoral immunity may be important in protection from *Serratia* infection and illness. In a murine model of

immunization against *S. marcescens*, only the transfer of antiserum and spleen cells from vaccinated mice increased bacterial clearance from the liver and survival after infection developed.⁶⁷ In nonphagocytic cells *in vitro*, *S. marcescens* can survive and even proliferate within autophagosome-like vacuoles by delaying or preventing fusion with lysosomes.⁴¹

Resistance of *S. marcescens* to aminoglycosides generally is plasmid mediated. Resistance to aminoglycosides may be conferred by one of several genes producing acetylating, phosphorylating, or adenylating enzymes.^{1,2,20,59,80} Risk for acquiring infection with aminoglycoside resistance increases with exposure to these agents.^{50,125} In some patients, repeated hospitalizations have shown greater importance, however, than aminoglycoside use as a risk factor for developing infection with resistant strains.⁶ High levels of resistance to penicillins and cephalosporins are mediated by one or more plasmids. Cephalosporin resistance also may be derived chromosomally (see also Chapter 102).^{28,46,78,93} Chromosomally mediated β -lactam resistance may be inducible in the presence of high levels of penicillin or cephalosporins, particularly when plasmid-derived β -lactamase is blocked by clavulanic acid.²¹

A group of researchers found and cloned a multidrug efflux pump of the major facilitator superfamily from *S. marcescens*.¹⁰⁸ Transposable plasmid elements may seem partly responsible for the rapid spread of multidrug resistance.^{99,100,105} In one survey, 2.6% of *S. marcescens* isolates were deemed “multidrug resistant,” defined as resistant to three or more classes of antimicrobial agents.³⁵ Plasmids conferring multidrug resistance are transferable from *S. marcescens* to *Klebsiella* spp. and may be responsible for sequential nosocomial outbreaks of different genera sharing common drug-resistance patterns.¹¹⁸ A report from Spain suggested probable *in vivo* transmission between *E. coli* and *S. marcescens* of a plasmid containing both β -lactamase and quinolone resistance genes.⁷² Carbapenem-resistant isolates have also been found.¹¹²

CLINICAL MANIFESTATIONS

First described in a patient with bronchiectasis as a cause of “blood-tinged” sputum colored by the organism,¹²³ *S. marcescens* commonly is associated with urinary tract, respiratory tract, central venous catheter, and bacteremic infections.² Other species, including *S. liquefaciens*, *S. ficaria*, *S. odorifera*, and *S. plymuthica*, are less common causes of disease.^{14,25,33,42,107}

Chromogenic *S. marcescens* was responsible for the historically interesting and reportedly benign “red diaper syndrome,” which persisted for 7 months in the infant of a genetics professor.¹²¹ In at least one series, the organism has been identified as one of the top five causes of neonatal sepsis⁵² and now is recognized as a major pathogen of compromised newborns. Disease in neonatal intensive care units is associated commonly with high rates of underlying respiratory illness.⁸⁷ Other preexisting risk factors include necrotizing enterocolitis, surgical procedures, intravenous catheters, prolonged intubation, and cardiac disease.¹⁴ Clinical illness shares features in common with other neonatal enteric pathogens; apnea, hypotension, and respiratory distress are seen frequently. Pneumonia with empyema has been reported.⁶² Meningitis occurs as a complication in 24% of cases of neonatal bacteremia,¹⁴ and antibiotic resistance may emerge during therapy for bacteremia or localized infection.²² Significant brain injury caused by ventriculitis, brain abscesses, or porencephalic cysts is observed in most infants with meningitis.^{22,68}

In older children and adults, *Serratia* spp. are isolated most frequently from the urinary tract.^{2,103} Instrumentation, catheterization, and clustering of susceptible individuals are important risk factors.^{6,23,59,101,104} By the 1970s, increased frequencies of serious infection, such as endocarditis, were noted in intravenous drug abusers.³⁰ In some series of respiratory and urinary tract infections, *S. marcescens* was observed to be associated more commonly with the complication of bacteremia than was any other enteric pathogen.^{61,66} As is true of other causes of gram-negative sepsis, *Serratia* sepsis characterized by shock, pneumonia, or hemorrhage confers a substantially poorer prognosis.^{15,17,102} The risk for these complications in cancer patients was observed by Saito and associates¹⁰² to be lower, however, than their previous experience with other pathogens, such as *E. coli* and *Pseudomonas aeruginosa*. When predictive factors of mortality were sought in 385 subjects with nosocomial bacteremia, *S. marcescens* was not an independent predictor of death.⁸¹ Other

infections caused by *Serratia* include soft tissue infections, abscesses, endophthalmitis (including a case occurring after septicemia in an infant),^{3,4} osteomyelitis and arthritis,¹¹⁷ spinal epidural abscess, ventriculoperitoneal shunt infection,²⁷ and peritonitis in dialysis patients.²⁹ A severe case of epiglottitis including fasciitis, myositis, and bacteremia was seen in a 58-year-old woman; prior cases were all in immune-compromised patients.⁸⁶ In one report, sternal osteomyelitis recurred 15 years after apparent successful treatment.⁹⁴ Necrotizing soft tissue infection with *Serratia* has been reported in a patient with rheumatoid arthritis who was on steroids, tacrolimus, and tocilizumab.⁷⁴

DIAGNOSIS

The diagnosis of *Serratia* infection relies primarily on isolation of organisms from clinical material. Nonspecific laboratory tests occasionally may be misleading. *Serratia* meningitis in a neonate may be accompanied by a normal cerebrospinal fluid white blood cell count or only a modest cerebrospinal fluid pleocytosis.²² Although *S. marcescens* is famous historically because of its chromogenic potential, most strains are nonpigmented. Hydrolysis of gelatin distinguishes *S. marcescens* from *Klebsiella* and *Enterobacter* in the clinical microbiology laboratory. The presence of ornithine decarboxylase and fermentation of sorbitol but not arabinose helps to differentiate further *S. marcescens* from other *Serratia* spp.⁵⁴ Biotyping,⁵³ DNA and RNA detection techniques,⁷⁰ and antimicrobial susceptibilities¹¹¹ can be used to characterize strains.

TREATMENT

Empirical decisions about antibiotic treatment of *Serratia* infection should rely on knowledge of hospital flora. Therapy should be tailored when susceptibilities are known. In newborns, meningitis and its complications should be suspected and interventions should be guided by imaging of the central nervous system. Imaging techniques may be useful in guiding needle aspiration of abscesses.⁸⁹ Recommended antibiotic therapy for neonatal meningitis is a cephalosporin and an aminoglycoside for susceptible strains. Mortality rates remain high (>45%) even with appropriate antibiotic management.²²

In older children and adults, reported response rates for bacteremic infection have been 75% for patients who received appropriate antibiotics, 22% for patients who received inappropriate antibiotics, and 29% for patients who received no antibiotics.¹⁰² Patients who continue to have positive blood culture results while receiving appropriate antibiotic therapy have a poor prognosis. In the review by Saito and associates¹⁰² of 118 patients with *Serratia* bacteremia, patients who received only an aminoglycoside had the poorest response rate among those who received appropriate therapy; patients who received a cephalosporin, alone or in combination, fared better. *Serratia* organisms generally have proved susceptible to third-generation cephalosporins in surveys of hospitals from North America.⁶⁰ The physician needs to be wary, however, of potential resistance to cephalosporins and penicillins owing to the production of extended-spectrum β -lactamases; this resistance may

arise during therapy. In an illustrative case, cefotaxime therapy failed to clear the spinal fluid in a child with a shunt infection; by day 17 of therapy, the cefotaxime MIC had risen from less than 1 $\mu\text{g/mL}$ to more than 16 $\mu\text{g/mL}$. Intermittent meropenem therapy also failed, but the patient was cured when meropenem was given by continuous infusion.²⁷ An extended-spectrum, metallo- β -lactamase that mediates resistance to imipenem has been described,⁹² but it is uncommon. Physicians should strongly consider empirical use of a carbapenem in combination with an aminoglycoside in critically ill patients.⁸⁸ A worldwide surveillance study from 2004 to 2009 suggested that more than 90% of *Serratia* strains were susceptible to meropenem, imipenem, and tigecycline.¹¹ However, outbreaks due to meropenem-resistant clones have also been described.¹¹⁶

Amikacin historically has been effective in the treatment of gentamicin-resistant strains.^{31,69} In 1985, amikacin was recommended as a first-line antibiotic for treatment of pediatric nosocomial infection when *Serratia* spp. or other enteric agents with resistance potential were suspected.¹¹⁰ Since the 1980s, however, outbreaks of *S. marcescens* infections caused by amikacin-resistant strains have been reported.⁹¹ Quinolones have been used successfully for treatment of organisms resistant to other agents,⁴⁷ but resistance to these drugs also has been identified.⁶⁵ Many multiresistant strains remain susceptible to tigecycline.^{71,85}

Cohorting and attempts to remove environmental sources of infection have been successful in ending epidemics but typically require several months.²⁶ Rarely neonatal intensive care units have been closed to admissions to halt epidemics.^{18,84}

Salmonella

Theresa J. Ochoa • Javier Santisteban-Ponce

Salmonellosis is a foodborne disease of global public health importance. *Salmonella* infections most often cause gastroenteritis, but can also cause invasive infections. Based on the clinical disease and pathogenesis, *Salmonella* organisms are classified as nontyphoidal *Salmonella* (NTS) and *Salmonella* associated with typhoid fever or enteric fever (*Salmonella enterica* ser. Typhi). NTS causes asymptomatic infection or carriage, gastroenteritis, bacteremia, or metastatic focal infections.

MICROBIOLOGY

Salmonellae are motile (owing to peritrichous flagella), nonencapsulated, gram-negative bacilli and facultative anaerobes of the Enterobacteriaceae family. *Salmonella* serotype is defined by the serogroup, the flagellar (H), and the virulence (Vi) antigens. H antigens can be either phase 1 (nonspecific) or phase 2 (specific). The Vi antigen, a heat-labile

Keywords:

Salmonella
Typhoid
Enteric fever

polysaccharide found on *S. ser. Typhi*, *S. ser. Dublin*, and *S. ser. Paratyphi C* may block agglutination caused by antibodies to O antigen. Serotyping is important for defining outbreaks, although it is most useful when an unusual type is associated with disease. When a common serotype is associated with an outbreak (e.g., *S. ser. Typhimurium*), biochemical phenotype, antibiogram, plasmid characterization, bacteriophage typing, outer-membrane protein analysis, pulsed-field gel electrophoresis, and randomly amplified polymorphic DNA may help determine whether a single-strain, common-source outbreak is in progress.

Based in host adaptability, *Salmonellae* are divided into three groups. Group 1 encompasses *Salmonella* highly adapted to humans and primates, group 2 identifies highly specific animal-adapted *Salmonella*, and group 3 includes those serovars not host adapted but capable of infecting both humans and a wide range of animals and consisting mainly of *Salmonella ser. Typhimurium* and *S. ser. Enteritidis*.⁷ Blood agar or chocolate agar supports their growth when they are present as the sole organisms in blood, cerebrospinal fluid (CSF), or joint fluid. For specimens containing mixed flora (e.g., stool), selective media such as *Salmonella-Shigella* (SS) agar or bismuth sulfate agar must be used.

TAXONOMY AND NOMENCLATURE

The genus *Salmonella* is divided into two species, *enterica* and *bongori*. The species *S. enterica* is further subdivided into six subspecies that are designated by taxonomic names: *enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae* and *indica*; these are sometimes abbreviated by Roman numerals. For example, *S. enterica* subsp. *enterica* is subspecies I.⁶⁷

Serotyping is used to differentiate isolates of *Salmonella* beyond the subspecies level. *Salmonella* serotypes are designated based on the immunoreactivity of two cell surface structures, the O and H antigens. A substantial amount of diversity exists in these two antigens, resulting in the designation of more than 2500 serotypes; about 60% belong to subspecies I. In the United States, 99% of reported human *Salmonella* isolates belong to subspecies I.⁶⁷ All *Salmonella* serotypes can be designated by a formula; subspecies I serotypes are also given a name (e.g., *Typhimurium*, *Enteritidis*, *Typhi*).

The complete, formal designation of a *Salmonella* serotype is its genus-species or genus-species-subspecies name, followed by “serotype” and the serotype name or formula. Some scientific journals require the formal designation of serotypes; others allow the use of an abbreviation. For example *Salmonella enterica* subsp. *enterica* serotype *Typhimurium*, is shortened to *Salmonella* serotype (ser.) *Typhimurium* or *Salmonella Typhimurium*. However, there is no international standard for abbreviating *Salmonella* serotypes.

In this chapter, we use the nomenclature of the Centers for Disease Control and Prevention (CDC) rather than either the complete name or the traditional clinical shorthand (Table 111.1). In hospital laboratories, *Salmonella ser. Choleraesuis* and *Salmonella ser. Typhi* are distinguished biochemically from other *Salmonella* spp. serogroup, based on O (somatic) antigen; organisms that are not *S. ser. Typhi* or *S. ser. Choleraesuis* are reported as *Salmonella* serogroup A, B, C1, D1,

and so on. Common *Salmonella* spp. and their serogroups are shown in Table 111.2. Complete serotyping is performed only in public health laboratories.

EPIDEMIOLOGY

Nontyphoidal *Salmonella*

Public Health Issues

In most of the world, the prevalence of *Salmonella* varies according to the water supply, waste disposal, food preparation practices, and climate. The incidence of NTS is 31 to 211 million gastroenteritis cases worldwide each year, causing 36,000 to 89,000 deaths globally and leading to the loss of 2 to 6 million of life-years.¹⁷¹ Most of the deaths occurred in the African region.¹⁷¹ Globally NTS is the worst foodborne hazard (2.5 to 6.3 million disability-adjusted-life-years).¹⁷¹ In the United States the incidence of the disease has increased steadily despite good public health interventions, while NTS-related mortality declined over years.⁹⁹ A more than sixfold increase in reported NTS infection in the United States has occurred during the past 40 years,³⁹¹ with an estimated 1.2 million illnesses, 23,000 hospitalizations, and 450 deaths annually during 2000 to 2008.^{69,341} This increase reflects industrial-scale food production and distribution,⁶⁶ misuse of antimicrobial agents (in humans and animals) that alter the competing gastrointestinal flora and induce multidrug-resistant strains of *Salmonella*,³⁸¹ and probably an increasing number of immunocompromised individuals in the population. Direct medical costs are estimated to be \$365 million annually.⁷⁰

Targeted interventions, including on-farm control measures, refrigeration, and education contributed to an important decrease in the incidence of *S. ser. Enteritidis* infections in the United States.²⁴⁸ From 1996 to 2011, serotypes *Typhimurium*, *Enteritidis*, *Newport*, *Heidelberg*, and *Javiana* jointly were 63% of isolates.⁵¹ While average incidence decreased for serotypes *Typhimurium* (16%) and *Heidelberg* (30%), increases in *Newport* (27%), *Javiana* (63%), *Saintpaul* (43%), and *Mississippi* (63%) were found from the second half of the time period.⁵¹

Globally 2.1 to 6.5 million cases per year are due to invasive NTS.¹⁹ In some developing countries, mortality rates of bacteremic NTS infections in infants remain at 20% or higher over the years, leading to 415,000 to 1.3 million deaths annually.^{19,155}

^aHuman infections with organisms in serogroups E4, F, G1, G2, H, and I and the O antigens not given serogroup designation (O17 through O67) are uncommon.

Significance of Animal Reservoirs and Other Food Sources

In contrast to *Shigella* spp., which infect only primates, nontyphoidal *Salmonella* spp. infect a variety of animals (including poultry, livestock, and pet reptiles and rodents).^{1,27,34,68,130,158,178,255,362} *Salmonella* has been isolated from flies, mites, and other arthropods taken from animal farms; it is able to multiply inside some insects and is transmitted within insects and to birds, rodents, and livestock.³⁹⁷ These arthropods, birds, and rodents could contribute to *Salmonella* transmission to wildlife.¹⁷⁶ Animals and animal products (including meat and dairy products),^{299,320,415} water,^{104,120,211,260} and infected humans³⁸⁴ can be the source of infection. *Salmonella* is the leading cause of foodborne illness in the United States and the second most common cause of death from foodborne pathogens.²⁴⁰ Spread of resistant organisms from food animals to humans has been shown.²⁷⁰ *Salmonella* spp. have been isolated from 50% of poultry,⁵³ 16% of pork, 5% of beef, and 40% of frozen egg products in retail stores. Slicing food with contaminated tools and surfaces transfers *Salmonella* in progressively decreasing amounts per slice, resulting in higher bacterial contamination for the first sliced portions.⁶⁵ Undercooked eggs (e.g., in Caesar salad, egg-dipped bread, and homemade eggnog) may be contaminated by organisms on the shell surface or transovarially directly through the egg yolk. Grade A shell eggs have been implicated in more than 40% of more recent outbreaks.²⁴⁰ Even in the absence of recognized outbreaks, undercooked eggs probably are important vehicles of infection.^{162,173,401}

The impact of *Salmonella* outbreaks was shown when milk contaminated with *S. ser. Typhimurium* was distributed in Chicago, Illinois. Reports estimated that more than 150,000 people became ill, with more than 16,000 culture-confirmed cases, 2777 individuals hospitalized, and 14 fatalities.³⁷ Ice cream, cream cakes, and mayonnaise commonly have been incriminated as the source of infections. Fruits and vegetables are vehicles reported less frequently in outbreaks but better identified and reported in recent years as a result of molecular methods and country-wide database reporting.^{40,135,175,236,245,315} From 2010 to 2014 the CDC's Foodborne Disease Outbreak Surveillance System reported 120 multistate foodborne disease outbreaks in the United States; *Salmonella* was the leading pathogen, responsible for 63 of these outbreaks.⁹⁴

Of the 10 most frequent *Salmonella* serovars causing disease in humans, eight are included within the 10 serovars most frequently identified in at least one of the major food-animal species.¹³⁷ Some serotypes are associated with particular reservoirs. *S. ser. Dublin* is associated with dairy cattle and is frequently found in individuals who drink raw milk.³⁶⁹ *S. ser. Choleraesuis* is associated with pigs.⁷⁷ *S. ser. Typhimurium* is associated with contact with pet rodents.³⁶² Infection with *S. ser. Marina* is associated with contact with pet iguanas.³⁶³ *Salmonella* group F, *S. ser. Typhimurium*, *S. ser. Muenchen*, *S. ser. Poona*, and *S. ser. Java* infections have been traced to pet turtles.²¹⁹ Reptiles, including rattlesnakes, are important *S. IIIa 18:z₄z₂₃*: (*Arizona hinshawii*) reservoirs and have been associated with almost all the 20 serovars isolated in animals in the United States during 2006.¹⁷⁷

Humans as a Reservoir

After infection occurs, NTS are excreted in feces for a median of 5 weeks. Children younger than 5 years may excrete the organisms for 20 weeks after having an illness, but older children and adults usually excrete *Salmonella* for less than 8 weeks. Up to 5% of children younger than 5 years have been found to excrete NTS for 1 year after disease⁵⁹; 2.2% to 2.7% of children in endemic settings have been found to excrete NTS.¹⁹² *S. ser. Typhi* may be excreted chronically, particularly in the presence of gallbladder disease and sustained by biofilms for decades.^{93,154,174,249} Food handlers who are excreting *Salmonella* spp. represent an important risk group. NTS infection index cases have been mapped to isolation of the same clones in 65% of children and adults living in the same household versus less than 2% of home rural environment samples.²⁰⁵ NTS may be excreted for longer periods in feces of children with primary immunodeficiency.²⁹³

Bacterial Characteristics Favoring Survival

Salmonella spp. survive refrigeration and sometimes heating; they may remain viable at ambient or reduced temperatures for weeks, even in low-moisture foods.³⁰⁸ *Salmonellae* may remain viable in foods after

cooking for less than 12 minutes at less than 65°C (140°F). *Salmonella* spp. are killed by heating to 54.4°C (130°F) for 1 hour or 60°C (140°F) for 15 minutes. Food industry ingredients with low water activity and high fat content provide a marked thermal resistance to *Salmonella*, making it necessary to use higher heating temperatures and longer times.³⁰⁸ *Salmonellae* survive for hours on the hands of slaughterhouse workers and in flour for nearly 1 year.³⁰¹ *S. ser. Tennessee* has been reported to remain viable for 2 to 8 days on glass, stainless steel, enameled surfaces, a rubber mattress, linen, and a rubber tabletop.³⁹⁹ Small *Salmonella* inoculates (<100 colony-forming units [cfu]/g) are able to survive 30 to 40 days in vacuum dust.¹⁷² Nosocomial infections have been related to contaminated medical equipment (e.g., endoscopes) and diagnostic or pharmacologic preparations, particularly those of animal origin (e.g., bile salts, pancreatic extracts, pepsin, and vitamins). *Salmonella*'s capability to form complex surface structures called biofilms in both host and nonhost environments is an important mechanism for survival and persistence.^{64,216,249} Biofilm formation increases resistance of *Salmonella* to disinfectants and even to antibiotics, resulting in 2000-fold resistance to ciprofloxacin in vitro.³⁵⁵

Relationship of Age to Risk for Disease

The highest incidence rates occur in children younger than 5 years (69.5 infections per 100,000 children),¹⁷¹ especially infants younger than 1 year, and in individuals older than 70 years. Among infants in the United States, the incidence of invasive salmonellosis (7.8 cases/100,000 inhabitants) is the highest within age groups.³⁹² Nursery outbreaks often can be traced to an infected mother,^{28,222} with subsequent spread occurring through health care personnel.^{340,400} The mother of the index case can be symptomatic^{136,199,328} or asymptomatic,⁴⁰⁰ recovering from recent infection,^{283,346} or a chronic carrier.³³⁷ Low-birth-weight infants seem to be at higher risk than full-term infants for acquiring *Salmonella* infection.^{33,340,400} The source of infection occasionally is contaminated food, but more often it is fomites (e.g., delivery room resuscitators,³²⁹ rectal thermometers,^{191,256} suction devices,²⁰⁹ water baths for heating formula,²⁰¹ soap dispensers,²⁶⁶ scales,^{6,35,400} tables,⁴⁰⁰ air-conditioning filters,⁴⁰⁰ and plumbing²⁶²). Outbreaks in nurseries often are extraordinarily difficult to stop. They have been reported to last months^{222,290,400} to years.^{136,262,366} Contamination sometimes can become so widespread that other areas of the hospital also experience cases.^{251,345} These outbreaks occur far more commonly with *Salmonella* than with other bacterial enteropathogens. Such outbreaks sometimes are caused by multiresistant *Salmonella*.²²² Multidrug-resistant *Salmonella* has been isolated from cockroaches found in a neonatal intensive care unit in Africa.³⁷⁵

Seasonality

Salmonella infection occurs throughout the year with a predilection for warm months,²²³ especially for some serotypes as Norwich, Javiana, Mississippi, and Newport,⁵¹ whereas serotypes Senftenberg, Mbandaka, Anatum, and Derby are distributed throughout the seasons.^{51,223}

Inoculum Size Required to Cause Disease

The estimated inoculum size required to cause symptomatic disease in healthy adult volunteers is 10³ to 10¹⁰ organisms,⁴⁷ but the number of organisms required to cause symptoms in infants and children probably is much lower. In contrast, large inocula are not required for *Shigella* infection, which occurs in adult volunteers exposed to only 10 organisms. In some outbreaks, very small inocula of *Salmonella* seem to have caused disease. Pharmacologic suppression of gastric acid secretion increases the risk for disease caused by *Salmonella*.³⁶ Large inocula (e.g., 10⁹ organisms) may cause severe symptoms, even in healthy children.³⁶⁹ The incubation period usually is 6 to 72 hours but depends on inoculum size, bacterial virulence, and host immunocompetence. Communicability parallels the duration of fecal excretion. The probability of salmonellosis occurring is increased when a member of the household is infected. Infants especially may be susceptible to acquiring *Salmonella* infection directly or indirectly from ill family members. Infants also may acquire infection via exposure to raw meat while riding in a grocery cart or while having contact with infected pets.¹⁹⁸ In a retrospective review of 187 infants younger than 1 year with *Salmonella* gastroenteritis, 39%

had at least one family contact with diarrhea, and 71% of the contacts had stool cultures positive for *Salmonella*.⁴⁰³ *Salmonella* spp. rarely have been isolated during studies of gastroenteritis in daycare centers, suggesting that larger inocula are required to cause illness in toddlers and older children.^{80,231,304}

Antibiotic Selection Pressure

Since the mid-1960s, *Salmonella* spp. have become increasingly resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX). Multiresistant strains have included *S. ser. Typhimurium*, which is the most common serotype in Europe and the United States. Multidrug-resistant *S. Typhimurium* phage type DT104 (DT104) rapidly emerged globally in the 1990s and became the most prevalent phage type isolated from humans and animals in many countries. DT104 is typically resistant to ampicillin, chloramphenicol, streptomycin, TMP-SMX, and tetracycline, along with its capacity to acquire additional resistance to other clinically important antimicrobials, including fluoroquinolones.^{152,227} Another important resistance trend among NTS isolates has been the development of resistance to fluoroquinolones, especially in Asia. The development of NTS isolates resistant to extended-spectrum cephalosporins, such as ceftriaxone, represents a substantial global public health concern.⁹⁸

Antibiotic resistance usually is transferable between organisms through plasmids that carry genes encoding resistance factors. Some serotype-specific virulence plasmids form hybrid plasmids through recombination with resistance plasmids or acquire gene cassettes consisting of multiple resistance genes. Such evolutionary events provide a virulent strain with the advantage of survival in an unfavorable drug environment.³⁶¹ Patients who are infected with antibiotic-resistant strains are more likely to be hospitalized, to be very young, to be black, and to have been exposed recently to antibiotic agents.²²⁴ Previous use of antimicrobial agents for treatment of other illnesses is a significant risk factor for acquiring multiresistant *Salmonella* infection.^{242,319}

In the United States, 30.5% of NTS isolates from blood from 1996 to 2007 were found resistant to at least one antimicrobial tested.⁹⁶ The National Antimicrobial Resistance Monitoring System (NARMS) during the years 2009–2011 reported 3% ceftriaxone resistance and 3% ciprofloxacin resistance in NTS *Salmonella* strains.⁷¹

Perhaps the most important factor is the overuse and misuse of antibiotics in animals raised for food.^{87,182,183,230,354} Subtherapeutic concentrations of antibiotics used to enhance growth and prevent infection in animals promote intestinal colonization by antibiotic-resistant bacteria, including *Salmonella*; these organisms may be found in feces and may contaminate instruments and meat at the time of slaughter.^{64,135} Plasmid analysis and antibiotic susceptibility patterns have linked *Salmonella* outbreaks to specific farms and slaughterhouses.^{182,183,270}

Salmonella Ser. Typhi

The CDC estimates that 22 million typhoid cases occur each year in the world, with an annual incidence varying from less than 10 to more than 1000 cases per 100,000 population.³³⁶ The global mortality estimates from typhoid also have been revised downward from 600,000 to 200,000, on the basis of regional extrapolations.⁹⁵ Globally the major nondiarrheal causes of foodborne deaths were due to *Salmonella Ser. Typhi* (~52,000) in 2010.¹⁷¹ *S. ser. Typhi* is the most common *Salmonella* isolate in many developing countries. Although the overall ratio of disease caused by *S. ser. Typhi* to disease caused by *S. ser. Paratyphi* is about 10:1, the proportion of *S. paratyphi* infections is increasing in some parts of the world,⁴² sometimes paralleling *S. ser. Typhi* isolations.⁹⁷ The human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) epidemic in Africa has been associated with a concomitant increase in community-acquired bacteremia caused by NTS.^{41,157} In the United States, approximately 1700 total cases were reported (one case per 100,000) in 1955. In 1988, approximately 400 total cases were reported (0.018 case per 100,000). Approximately 28% of infections occurred in individuals 19 years old or younger. Frequently, the highest incidence is stated as occurring in individuals 5 to 12 years of age. More recent population-based studies from South Asia and India suggest, however, that the incidence is highest in children younger than 5 years, with higher rates of complications and hospitalization.^{42,349}

In the United States, individuals traveling to developing countries are a high-risk group; 62% to 81% of infections are related to foreign travel, especially to Mexico, India, the Philippines, Pakistan, El Salvador, and Haiti. Of these areas, the Indian subcontinent has the highest incidence of typhoid among travelers.^{4,65,264,333}

Reservoir

Humans are the reservoir for *S. ser. Typhi*; infection implies direct or indirect contact with an infected person. Animal products transmit *S. ser. Typhi* if they are contaminated by infected humans during processing. The most common mode of transmission is food or water contaminated by human feces. Waterborne typhoid fever epidemics are especially important. Congenital transmission can occur from a bacteremic mother to her fetus transplacentally^{269,342} or at the time of delivery.²⁶⁹

Relevance of Inoculum Size to Disease

As with NTS, more than 10⁵ organisms are required to cause clinical illness in adults.^{185,186}

Antibiotic Resistance

The worldwide frequency of antibiotic-resistant *S. ser. Typhi* has been increasing since the 1960s.³⁵¹ Drug resistance in *Salmonella Typhi* (resistance or partial resistance to ciprofloxacin) has increased significantly from about 20% in 1999 to more than 70% in 2011.⁷⁰ Travel-associated infections are more likely to be antibiotic resistant. The CDC has reported some level of resistance (resistance or partial resistance) to ciprofloxacin in 67% of *Salmonella Typhi* tested (3-year average, 2009–11). The CDC has not yet seen resistance to ceftriaxone or azithromycin in the United States, but this has been reported in other parts of the world. Resistant infections are likely to cost more than susceptible infections because illness may last longer.⁷⁰ Extensive protracted outbreaks have been reported throughout Asia, the Middle East, and Central and South America. These outbreaks may have been related to widespread and inappropriate use of antimicrobial agents in these areas. After sporadic outbreaks of chloramphenicol-resistant typhoid between 1970 and 1985, many strains of *S. ser. Typhi* developed plasmid-mediated, multidrug resistance to the three primary antimicrobials used (i.e., ampicillin, chloramphenicol, and TMP-SMX).³²⁷ This pattern of simultaneous resistance of *S. ser. Typhi* to formerly recommended first-line antimicrobials (i.e., ampicillin, chloramphenicol, and TMP-SMX) is defined as multidrug-resistant typhoid fever.⁴⁰⁵ Chromosomally acquired quinolone resistance in *S. ser. Typhi* and *S. ser. Paratyphi* has been described more frequently in some parts of Asia and the rest of the world, possibly related to the widespread and indiscriminate use of quinolones.^{316,348} With the advent of quinolone resistance, third-generation cephalosporins were used for treatment, followed initially by occasional reports of resistance.⁴¹⁶ Today *Salmonella* serovar *Typhi* isolates displaying resistance to extended-spectrum cephalosporins are described worldwide. For example, extended-spectrum β -lactamase (ESBL) enzymes of the SHV-12 and CTX-M types and an AmpC β -lactamase of the ACC-1 type have been reported among isolates from Germany, the Philippines, Bangladesh, and India.⁹⁸ Similarly there have been sporadic reports of azithromycin resistance.¹⁹⁵

PATHOPHYSIOLOGY

The severity and outcome of *Salmonella* infections depend on the combination of the virulence of the infecting bacterial strain, the infectious dose, the route of infection, and the genetic makeup and immunologic status of the host.

Salmonella can (1) adhere to, invade, and multiply in intestinal epithelium; (2) produce cholera toxin–like enterotoxin that increases cyclic adenosine monophosphate levels within intestinal crypt cells, causing a net efflux of electrolytes and water into the intestinal lumen; (3) be taken up by M cells overlying Peyer's patches of the distal ileum and proximal colon; (4) survive in macrophages of Peyer's patches, mesenteric lymph nodes, and the extraintestinal reticuloendothelial system; and (5) survive in the bloodstream.^{134,136,145} Specific genes encode virulence factors necessary for each step in these processes and for specific disease manifestations (Table 111.3).

TABLE 111.3 Putative Pathophysiologic Basis of Selected Clinical Features of Salmonellosis

Disease Manifestation	Mechanisms and Bacterial Genes
Bloody diarrhea	<i>sipA-D</i> —mediated invasion and interleukin-8—mediated inflammation
Watery diarrhea	<i>stn</i> enterotoxin (cholera-like toxin) <i>SopB</i> -mediated intestinal inflammation and fluid secretion Serotypes that induce transepithelial polymorphonuclear leukocyte migration (e.g., <i>S. ser. Typhimurium</i>) are more likely to cause diarrhea than are serotypes that do not (e.g., <i>S. ser. Typhi</i>)
Bacteremia	<i>viaB</i> (Vi synthesis) capsular antigen interferes with C3 binding (<i>S. ser. Typhi</i> , <i>S. ser. Dublin</i> , <i>S. ser. Paratyphi C</i>) <i>rck</i> resistance to serum complement (virulence plasmid encoded) <i>rfb</i> encodes lipopolysaccharide synthesis; lipopolysaccharide contributes to persistence of bacteremia
Relapses, prolonged fever, failure of certain antibiotics	Survival in macrophages (<i>sseABC</i> , <i>spiC</i> , <i>mgfCB</i> , cytotoxin and virulence plasmid genes <i>spvRABCD</i>)

Pathologic findings in *S. ser. Typhi* infection include hypertrophy and hyperplasia of the intestinal and mesenteric lymphoid tissues, liver, and spleen. In contrast, *S. ser. Typhimurium* and other nontyphoidal serotypes cause diffuse colitis, mucosal edema, and crypt abscesses as the major pathologic abnormalities.^{53,103}

Some virulence genes are shared by all *Salmonella* strains, whereas others are serotype-specific. Differences in invasiveness of various serotypes exist. *S. ser. Typhi*, *S. ser. Choleraesuis*, *S. ser. Heidelberg*,^{190,258} and *S. ser. Dublin*³⁶⁹ are more likely to enter the blood and to seed distant sites. Virulence plasmids have been identified in *S. ser. Typhi*, *S. ser. Typhimurium*, and *S. ser. Dublin*.²⁹ The presence of virulence plasmids seems to be more common in blood isolates of *S. ser. Typhimurium* than in fecal isolates (76% vs. 42%).¹²⁸

Nursery outbreaks of *Salmonella* have shown dramatically the variability in severity of illness related to strain or serotype. In nursery outbreaks of *S. ser. Oranienburg*³⁶⁶ and *S. ser. Newport*,²²² grossly bloody stools were found in 76% to 90% of infected infants, with 10% to 11% febrile and only 9% to 11% asymptomatic. Watery, green, nonbloody diarrhea has been common with *S. ser. Typhimurium*,² *S. ser. Virchow*,³²⁵ and *S. ser. Nienstedten*.³⁴⁵ A high frequency of asymptomatic infections has been seen during nursery outbreaks with *S. ser. Heidelberg* (38% asymptomatic),³³ *S. ser. Virchow* (42% asymptomatic),³²⁵ and *S. ser. Tennessee* (100% asymptomatic).⁴⁰⁰

Which genes are required for disease in humans versus animals remains unclear. *S. ser. Typhimurium* has genes that allow it to cause a nondiarrheal typhoidal illness in mice; in humans, it typically causes symptoms related primarily to intestinal involvement. An estimated more than 200 genes determine *S. ser. Typhimurium* virulence in mice. The clinical variability in host range and disease manifestations is due to the fact that *Salmonella* strains vary in their possession and expression of virulence genes.²⁴⁸

Salmonella has developed two complex virulence functions to actively interact with the host and modify host cell functions. These interactions are hallmarks of *Salmonella* pathogenesis: (1) *Salmonella* infects cells of the gastrointestinal epithelium and is thus able to invade nonphagocytic cells, and (2) *Salmonella* may survive and replicate inside the phagocytes. Of critical importance for these interactions are the *Salmonella* pathogenicity islands (SPI), in particular SPI-1 (invasion and penetration of the gastrointestinal epithelium) and SPI-2 (systemic spread and colonization of host organs) (Fig. 111.1).¹⁶⁹ Both SPIs encode a molecular apparatus termed type III secretion system (TTSS). This apparatus is structurally and functionally related to the flagella assembly systems and typically contains more than 20 different protein subunits located in the inner and outer membrane and in the periplasm and cytoplasm of the bacterial cells.¹⁶⁹ TTSSs are capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.⁸⁵

Genes relevant to the intestinal phase of illness are encoded primarily in SPI-1. The *invA-H* chromosomal genes are necessary for adherence to and invasion of intestinal mucosal cells¹³³; most of the genes described so far seem to be involved in secretion or transport of virulence proteins.^{160,383} Genes related to the *Shigella* invasion plasmid antigens

(*ipaA-D*) have been described in *Salmonella* spp.^{203,204}; these *Salmonella* genes (*sipA-D*) encode the proteins that interact with host cells to cause bacterial uptake and intracellular movement. The major TTSS effector proteins used to invade epithelial cells and induce inflammation in the *Salmonella typhimurium* mouse model are SipA, SopB, SopE, and SopE2.²⁰² Although initially characterized as an invasiveness island, SPI-1 has additional functions related to the activation of the innate immune pathway, including (1) induction of polymorphonuclear recruitment across the intestinal epithelium by the SPI-1 secreted effect SipA, (2) activation of nuclear factor- κ B signaling by the concerted activity of SPI-1 translocated effectors, and (3) activation of caspase-1-mediated interleukin-1 β (IL- β)/IL-18 activation and proinflammatory cell death by the SPI-1 translocator effector SipB.⁸⁵

The role of host cells in the invasion process is complex. After *S. ser. Typhimurium* comes in contact with epithelial cells, activation of epidermal growth factor receptor occurs, which activates a kinase that turns on phospholipase A₂ so that arachidonic acid is generated. Arachidonic acid is converted to leukotriene D₄, which opens calcium channels and causes membrane ruffling, cytoskeletal changes, and uptake of bacteria.¹³³ Nonphagocytic cells, including epithelial cells, are adapted poorly for killing of internalized bacteria. Not only do *Salmonella* spp. survive in vacuoles within epithelial cells, but they also can replicate actively.¹³⁴ *S. ser. Typhi* survives better in human than in mouse macrophages, whereas *S. ser. Typhimurium* survives better in mouse macrophages.^{38,58,343} *Salmonella* is capable of infecting a wide variety of cells, including dendritic cells, macrophages, hepatocytes, neutrophils, colonocytes, and other epithelial cells. In vitro, within minutes of contact with cells, *Salmonella* organisms are internalized and take up residence in a unique membrane-bound compartment distinct from a phagosome or lysosome, the *Salmonella*-containing vacuole.¹⁵⁶ Live neutrophils recruited during acute *Salmonella* colitis engulf pathogens in the gut lumen and may thus actively engage in shaping the environment of pathogens and commensals in the inflamed gut.²³⁵

SPI-2 is essential for intracellular parasitism and systemic virulence in murine typhoid and for evasion of phagocyte oxidase machinery of the host.³⁸⁸ Intracellular replication occurs in a specialized membrane compartment, the *Salmonella*-containing vacuole, and depends on translocation of approximately 30 effector proteins via the SPI-2 TTSS into the host endomembrane system and cytoplasm.¹²⁹ SPI-2 has additional roles in inflammatory disease, such as induction of cyclooxygenase and modulation of host cytokine expression and signaling. In addition, SPI-2 function affects antimicrobial defense mechanisms of the host, intracellular transport processes, integrity and function of the cytoskeleton, and host cell death.²¹⁷ SPI-2 is crucial for early and complete induction of enterocolitis and systemic disease.⁸⁵

Several pathogen-associated molecular patterns of pathophysiologic importance are presented by *Salmonella* during infection, principally lipopolysaccharides and flagellin. The activation of Toll-like receptor 4 (TLR4) in response to *Salmonella* lipopolysaccharides is essential for inducing host responses.³⁸⁷ *Salmonella* flagellin is a potent inducer of host inflammation in polarized epithelial monolayers when delivered to the basolateral surface of the epithelium. When delivered there, *Salmonella* flagellin induces IL-8 secretion by stimulating basolateral

FIG. 111.1 Host-pathogen interactions during pathogenesis of *Salmonella* infection. SPI1 function is required for the initial stages of salmonellosis (i.e., the entry of *Salmonella* into nonphagocytic cells by triggering invasion and the penetration of the gastrointestinal epithelium). Furthermore, SPI1 function is required for the onset of diarrheal symptoms during localized gastrointestinal infections. The function of SPI2 is required for later stages of the infection (i.e., systemic spread and the colonization of host organs). The role of SPI2 for survival and replication in host phagocytes appears to be essential for this phase of pathogenesis. (From Hansen-Wester I, Hensel M. *Salmonella* pathogenicity islands encoding type III secretion systems. *Microbes Infect.* 2001;3:549–59.)

TLR5.⁴¹⁷ Flagellin stimulation of innate immune responses is crucial for intestinal inflammation but not for murine typhoid.⁸⁵

The development of diarrhea depends on host and pathogen factors. An influx of polymorphonuclear leukocytes into the mucosa must occur for diarrhea to develop.³⁹⁸ Neutropenic animals fail to develop fluid secretion when they are infected with *Salmonella*³⁹⁸; infiltration of leukocytes is thought to trigger production of prostaglandin because fluid secretion can be blocked by indomethacin.¹⁴⁶ A cholera toxin-like enterotoxin is made by approximately two-thirds of *Salmonella* strains, including *S. ser. Typhimurium* and *S. ser. Typhi*.¹⁹⁶

For most NTS strains, infection does not extend beyond the lamina propria and the local lymphatics. In contrast, *S. ser. Typhi*, *S. ser. Dublin*, and *S. ser. Choleraesuis* rapidly invade the bloodstream, with little intestinal involvement. Some virulence genes confer a survival advantage to the organisms if they get into the extraintestinal milieu. Vi capsular antigen present in *S. ser. Typhi*, *S. ser. Dublin*, and *S. ser. Paratyphi C* interferes with C3 binding. Mutations in lipopolysaccharide genes decrease invasiveness of *S. ser. Typhi* and *S. ser. Choleraesuis*, but not of *S. ser. Typhimurium*.^{134,277} *S. ser. Dublin*, *S. ser. Typhimurium*, and *S. ser. Enteritidis* have virulence genes that confer resistance to complement by preventing the formation and insertion of the C5b-9 membrane attack complex.

The mechanisms governing homeostasis and immune defense are of great importance for *Salmonella* infection. *Salmonella* uses multiple strategies to evade and modulate host innate and adaptive immune responses, to persist in the presence of a robust immune response.²⁷³ Chronically infected hosts are often asymptomatic and transmit disease to naïve hosts via fecal shedding of bacteria, thereby serving as a critical

reservoir for disease. The ability of *Salmonella* to persist depends on a balance between immune responses that lead to the clearance of the pathogen and avoidance of damage to host tissues.³³⁰ In addition, the intestinal microbiota plays a critical role in controlling *Salmonella* infection, disease, and transmissibility.²⁷³ However the molecular nature of the homeostatic interactions, the pathogen's ability to overcome colonization resistance, and the triggering of native and adaptive mucosal immune responses are still poorly understood.^{201,202}

Host Factors

Multiple host defense strategies have evolved to deal with the bacteria virulence factors; host susceptibility often can be related directly to defects in these defense mechanisms (Table 111.4). The host tries to kill ingested organisms in the stomach, to inhibit their growth in the gut, to limit their spread beyond the intestine, and to clear them by immune mechanisms. At a pH of 2.0, most *Salmonella* spp. are killed rapidly.¹⁴⁴ When gastric pH is increased by oral administration of antacid, susceptibility increases.^{143,185,186,319} A *Salmonella* inoculum ingested in water passes through the stomach more rapidly than when the same inoculum is ingested in food. Rapid transit through the small bowel decreases the contact time of organisms with the mucosa. Patients with decreased intestinal motility caused by medication or anatomic factors have increased severity and complications and may have a prolonged carrier state. Prior antimicrobial exposure increases the risk for incurring infection with antimicrobial-susceptible and antimicrobial-resistant strains of *Salmonella*.³⁰⁰ The normal flora may compete for substrates, lower the local pH by production of short-chain fatty acids, and produce antibacterial substances such as colicins. Some patients with

TABLE 111.4 Susceptibility to *Salmonella* spp. Infection

Patient Group at Risk	Mechanism
Newborn	Achlorhydria, rapid gastric emptying Poorly developed cell-mediated immunity Complement deficiency Immunoglobulin deficiency in premature infants
Sickle-cell anemia	Reticuloendothelial system overload owing to hemolysis Functional asplenia Tissue infarcts Defective opsonization
Neutropenia (congenital or acquired)	Polymorphonuclear neutrophils needed for killing
Chronic granulomatous disease	Defective killing by polymorphonuclear neutrophils
Defects of immune system IL-12/interferon- γ axis	Defective signaling resulting in failure to activate macrophages and recurrent/persistent infection by nontyphoid <i>Salmonella</i>
Acquired immunodeficiency syndrome	Low CD4 Effects of malnutrition on cell-mediated immunity Survival of organisms in macrophages (owing to <i>Salmonella</i> genes <i>PhoP/PhoQ</i> , <i>spvA-D</i> , <i>R</i>)
Organ transplantation, immunosuppression	Defective cell-mediated immunity
Gastrectomy	Loss of stomach acid barrier
Malaria	Reticuloendothelial overload during hemolysis Abnormal complement levels Abnormal macrophage function
Bartonellosis (verruca peruana)	Reticuloendothelial overload during hemolysis
Schistosomiasis	<i>Salmonella</i> sequestered in schistosomes protected from host defenses and antibiotics

gastroenteritis have progression or exacerbation of symptoms when antibiotics are given.³²⁴

Children with compromised immune systems are at increased risk for serious focal infections. *Salmonella* organisms are able to survive in macrophages but not in polymorphonuclear leukocytes. Patients with neutropenia (e.g., congenital or related to chemotherapy) or neutrophil dysfunction (e.g., chronic granulomatous disease) are at high risk for development of disseminated infection. Patients who have been bacteremic with a NTS strain are at increased risk for having a relapse if leukopenia is present.¹⁴¹

An increased risk for acquiring disease exists in settings in which reticuloendothelial function or cell-mediated immunity is impaired^{282,353} or immature.²⁸⁰ Hemolytic anemias are thought to cause reticuloendothelial overload. Children with sickle-cell anemia are at risk for developing bacteremia and osteomyelitis, and *Salmonella* spp. is 2 to 5 times more common than *Staphylococcus aureus* in these patients.^{5,5,247,364,410} Within febrile children with sickle-cell anemia, *Salmonella* spp. was found in 3.1% of positive urine cultures.²⁵⁴ Children with sickle-cell and S-Thal also sometimes develop osteomyelitis.⁸⁶ Patients with sickle-cell anemia have complement defects and defects in opsonization of *S. ser. Typhimurium*.¹⁶⁸ Newborns also have complement deficiencies that may explain the high frequency of *Salmonella* infection in newborns and the susceptibility of newborns to bacteremic complications seldom seen in normal hosts.

Malaria predisposes to salmonellosis by multiple mechanisms.²⁴¹ Schistosomiasis predisposes to development of *Salmonella* infections and prolonged bacteremia³¹⁹; reticuloendothelial cell killing of *Salmonella*

is impaired, and *Salmonella* colonizes the schistosomes. Pili on *Salmonella* adhere to the surface of *Schistosoma mansoni* and *Schistosoma haematobium*.²³⁷ In Gabonese children with bacteremic NTS infection, rectal biopsy specimens showed the eggs of *Schistosoma intercalatum* in 90% of cases.¹⁴²

Immune Response

The innate immune system provides the first line of defense against invading microorganisms by inducing a variety of inflammatory and antimicrobial responses. A distinctive feature of *Salmonella* is that it has not only adapted to survive in a strong inflammatory environment, but it also uses this adaptation as a strategy to gain a growth advantage over the intestinal microbiota. The gastric innate immune response to *Salmonella* is complex. First, following the invasion of the mucosa, the presence of *Salmonella* is detected by pattern recognition receptors. Extracellular *Salmonella* are detected by TLRs inducing a transcriptional response leading to the expression of proinflammatory cytokines such as IL-23. Intracellular *Salmonella* activate NOD-like receptors that can induce IL-23 expression, as well as the assembly of NLR4/NLRP3 inflammasomes that activate caspase-1, promoting the secretion of mature IL-1 β and IL-18. SPI-1-mediated activation of caspase-1 in epithelial cells might contribute to IL-18 secretion. Furthermore IL-18 and IL-23 amplify the inflammatory response by paracrine signaling. IL-18 induces the release of IFN γ from T cells, and IL-23 induces the release of IL-22 and IL-17. These cytokines induce the increased production of mucins and antimicrobial peptides and promote the release of CXCL chemokines, leading to an influx of neutrophils into the mucosa.⁵⁶

Cell-mediated immunity generally is thought to be more important than humoral immunity in clearance of *Salmonella* organisms. T-cell activation of macrophages is necessary to kill intracellular *Salmonella* organisms.²⁴⁴ Oral immunization with an attenuated typhoid vaccine primes lymphocytes to produce cytokines typical of a T_H1 response (high interferon [IFN- γ]/low IL-4) to the flagellar antigen.³⁶⁷ Healthy individuals vaccinated with either oral or parenteral typhoid vaccines develop antibody-dependent cellular cytotoxicity mediated by IgA, IgG, or both.¹⁰⁰ Studies of serum and secretory antibodies to O and H antigens have not shown protection, however; relapses of typhoid fever have occurred despite high antibody titers. Immunity may be short lived. In a study of 14 individuals (17 to 28 years old) with acute typhoid fever, cell-mediated immunity persisted for 16 weeks; intestinal secretory IgA persisted for 48 weeks; and IgG, IgM, and anti-O and anti-H agglutinins persisted for 2 years, 16 weeks, 16 weeks, and 36 weeks, respectively.³³⁹

Cytokines play a crucial role in initiating and regulating the innate and adaptive immune response against *Salmonella*. These bacteria can trigger synthesis of cytokines and chemokines in epithelial cells, macrophages, and dendritic cells. The consequences of cytokine activation vary. Although IFN- γ , IL-12, tumor necrosis factor- α , IL-18, transforming growth factor- β , and CCL2 have protective functions during *Salmonella* infection, IL-4 and IL-10 interfere with host defenses.¹¹⁷ The main immunologic mechanisms that control the course of *Salmonella* infection in mice are described in Fig. 111.2.²⁵²

Impaired cell-mediated immunity probably explains the high frequency of bacteremia with nontyphoidal *Salmonella* strains in children with HIV infection³³² and with malnutrition.³⁵⁰ Defective cell-mediated immunity can be congenital or acquired (from tumors,¹⁶⁵ collagen vascular disease, organ transplantation,¹¹⁹ chemotherapy, glucocorticosteroids).³¹³ Inherited deficiency in the IL-12/IL-23/IFN- γ pathway results in susceptibility to recurrent *Salmonella* and *Mycobacterium* infections.¹⁰⁹ Defects have been described in which patients have mutations in IL-12, IL-12 receptor, IL-23, IL-23 receptor, IFN- γ receptor, or signal transducer and activator of transcription (STAT). Complete and partial deficiency syndromes have been described.^{15,21,200} Isolated persistent or recurrent nontyphoidal *Salmonella* infection without history of infectious episodes by other microorganisms has been reported in 15% of children with deficiency of the β -1 receptor for IL-12.³⁸

Humoral immunity is less important.⁴⁹ Preterm neonates who are infected with *S. ser. Typhimurium* may have a lower risk for developing complications (e.g., intestinal perforation, meningitis, endophthalmitis, sepsis, and pyelitis) if they are given intravenous immunoglobulin plus

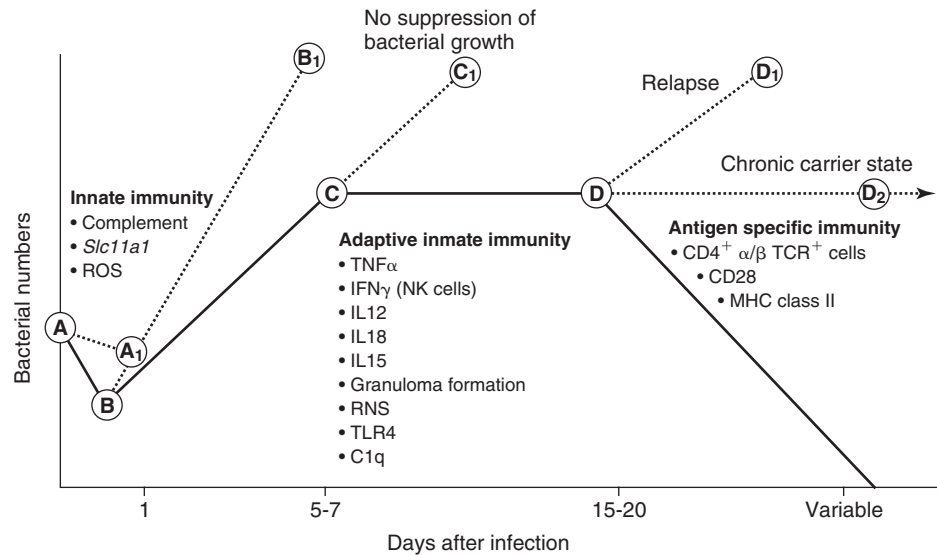

FIG. 111.2 Immunologic mechanisms that control the progression of a sublethal *Salmonella enterica* infection in the mouse model. The solid line shows the course of a sublethal infection in wild-type immunocompetent mice. The dotted lines show the course of the infection when immunologic mechanisms required at points A→D are absent. Lack of complement and/or reactive oxygen species (ROS) affects the early blood clearance and killing of the bacteria with a shift of the growth curve from A→B to A→A1. The *Slc11a1* gene and ROS influence the net growth rate, and their absence determines a shift of the curve from B→C to B→B1. Point C coincides with the onset of the adaptive innate immunity response. The lack of any of the immunologic factors that form part of adaptive innate immunity determines failure to suppress bacterial growth in the tissues (C→D) and the unrestrained progression of the infection process (C→C1). Point D coincides with the intervention of antigen-specific immunity that is required to clear the infection and prevent relapse (D→D1) of the establishment of a chronic carrier state (D→D2). (From Mastroeni P, Maskell D, editors. *Salmonella infections*. Cambridge, MA: Cambridge University Press; 2006:209).

cefoperazone than if given cefoperazone alone (16% vs. 82%); the mortality rate also is decreased (12% vs. 41%).¹⁵³

CLINICAL MANIFESTATIONS

Salmonella spp. may cause acute or chronic asymptomatic infection. Symptomatic infections include acute gastroenteritis, bacteremia with or without local suppuration, and enteric fever.

Acute Asymptomatic Infection

Asymptomatic infections are identified by stool cultures obtained during prospective or epidemiologic investigations. Detections range from no signal by polymerase chain reaction (PCR) in 410 schoolchildren from rural Madagascar¹⁴⁰ to 74% positive stool cultures for NTS in Mexican infants.⁹²

Acute Gastroenteritis

The most common clinical illness caused by *Salmonella* infection is gastroenteritis. Nausea, vomiting, and crampy abdominal pain begin 6 to 72 hours (median, 24 hours) after ingestion of contaminated food or water. The abdominal pain may be severe enough to suggest appendicitis. Diarrhea usually is moderate in volume and, depending on the serotype, may contain blood. Dysentery is more common in children from developed countries than in those from developing regions.³⁰³ Headaches, malaise, myalgias, and fevers are common. These symptoms usually resolve in approximately 1 week without antibiotic therapy; symptoms may persist in very young patients and patients with underlying diseases. In neonates, loose, green, mucous stools or, less often, bloody diarrhea is seen; fever is common with *Salmonella* gastroenteritis during the first months of life.¹⁹⁰ Reactive arthritis develops rarely in children after having *Salmonella* gastroenteritis.²⁰⁸

Bacteremia With or Without Metastatic Focal Infection

Some *Salmonella* serotypes (e.g., S. ser. Typhi; S. ser. Choleraesuis; S. ser. Paratyphi A, B, and C; S. ser. Heidelberg; S. ser. Typhimurium; S.

ser. Enteritidis; S. ser. Saint-Paul; S. ser. Newport; S. ser. Panama; and S. ser. Dublin) have a propensity to invade the bloodstream; others (e.g., S. ser. Tennessee and S. ser. Weltevreden)⁴⁰⁵ rarely seem to cause bacteremia. *Salmonella* has been found as one cause of occult bacteremia in infants and children,^{10,213} and, when not treated with appropriate parenteral antibiotics, 45% to 68% of infected children developed persistent *Salmonella* bacteremia.²¹⁸ *Salmonella* is also found within cases of clinically suspected community-acquired invasive bacterial disease in children from tropical regions.¹⁸ Fever, chills, diaphoresis, myalgias, anorexia, and weight loss may last for days or weeks. Stool cultures may be negative. A child sometimes can have afebrile diarrhea and yet be bacteremic for several days.²⁰⁶ Warm climate, previous gastrointestinal disease, and recent exposure to antibiotics are some reported risk factors for bacteremia in children.¹⁷⁰ Severe malnutrition, HIV infection, prolonged illness, and recent hospital admission are risk factors for nontyphoidal *Salmonella* bacteremia in developing countries.⁵⁴ The true frequency of bacteremia is unclear. Depending on the patient's age, geographic location, and nature of the study (prospective vs. retrospective), 2% to 45% of infections are bacteremic.^{101,190,258,280,350,376,404,405,413} Bacteremia probably occurs more commonly in newborns (in some studies 30% to 50%) than in older children,¹⁹⁰ although this is debatable.²⁵⁸ The true risk for bacteremia developing in the first year of life is likely to be 2% to 6%.^{101,376}

Palpable purpura and leukocytoclastic vasculitis have been described with bacteremia and sepsis due to *Salmonella*.^{12,90,132,418} In the preantibiotic era this was an ominous sign.³²³ Recently, it has been described in patients affected by a defect in IL-12 β_1 receptor (IL-12/IFN- γ axis).^{13,131,220,334} A high index of suspicion for defects in this axis is recommended because the usual panels for immunodeficiency are within normal in this group of conditions.^{13,38,285,382}

Hemolytic anemia, especially sickle-cell anemia, is associated with a high risk for development of *Salmonella* bacteremia.²⁷⁶ Persistent or recurrent bacteremia occurs in patients with AIDS, schistosomiasis, and intravascular focal infection.^{276,284} Immunocompromised adults who become bacteremic with *Salmonella* are more likely to do so without

having had preceding gastroenteritis and to have a high mortality rate.¹⁶⁷ Children more typically are relatively immunocompetent; most often, they develop bacteremia associated with diarrhea and have a much better prognosis.^{226,258} In a large study in African children, NTS were the second most common cause of community-acquired bacteremia in all children and in HIV-positive patients.⁴¹ The risk for development of focal infections during bacteremia is higher (36%) in children with underlying conditions than in previously healthy children (2.5%).⁴¹⁴

Focal suppurative infections may occur almost anywhere (Box 111.1); the most common sites are bones (particularly in sickle-cell anemia)^{267,318} and the central nervous system.^{57,113,212,238,322,414} Meningitis has a high morbidity, with acute hydrocephalus, seizures, ventriculitis, abscesses, subdural empyema, and cerebral infarction.⁴¹¹ Long-term neurologic sequelae include developmental delay, which could be severe; motor disabilities (i.e., cranial nerve palsy, hemiparesis, quadriplegia); chronic hydrocephalus; epilepsy; visual and auditory impairment; and athetosis.^{87,292,411} Neurologic sequelae are particularly common in infants with delayed presentation, prolonged fever (>10 days) or seizures during hospitalization, and marked alteration of consciousness on admission.^{188,292,411} Mortality rates from meningitis were 40% to 60% before the introduction of third-generation cephalosporins, fluoroquinolones, and carbapenems. With the use of these antibiotics, the mortality rate has decreased to almost 10% but still carries a high rate of sequelae.^{292,411} Relapses even after prolonged therapy occur commonly (reflecting the intracellular localization of *Salmonella* and the difficulty of achieving adequate intracellular levels of antibiotics). Of NTS meningitis, 50% to 75% occur in the first 4 months of life.^{86,292} The serotypes causing meningitis, including *S. ser. Typhimurium*, *S. ser. Heidelberg*, *S. ser. Enteritidis*, *S. ser. Saint-Paul*, *S. ser. Havana*, *S. ser. Oranienburg*, *S. ser. Newport*, and *S. ser. Panama*,^{86,403} are commonly associated with bacteremia. In infants, complications include pneumonia,³³ osteomyelitis,^{107,215,410} septic arthritis,^{33,50,340} pericarditis,^{9,48,166,257} pyelitis,³⁶⁶ peritonitis,^{2,389} otitis media,² mastitis,^{279,344} cholecystitis,^{164,221} endophthalmitis,⁹¹ cutaneous abscesses,^{32,233,311} phlebitis²³³ and infected cephalohematoma.¹⁰⁷ In adults and occasionally in older children, femoral and distal aorta (mycotic aneurysms),^{86,126} heart valves,⁸⁶ mediastinum,¹²⁶ scrotum,³⁷⁹ testicles,⁸⁶ prostate,³³⁸ vulva,⁴⁶ vagina,⁴⁶ ovaries,⁸⁶ and fallopian tubes³³⁸ also may be infected.

Hemolytic-uremic syndrome associated with *S. ser. Typhimurium*^{114,253} and *S. ser. Typhi*³¹ has been reported. Because the cytotoxins produced by various *Salmonella* strains are distinct immunologically from Shiga toxin produced by *Shigella dysenteriae* 1 and the Shiga toxins produced by enterohemorrhagic *Escherichia coli*,²² the association of hemolytic-uremic syndrome with salmonellosis may represent undiagnosed dual infection with toxin-producing organisms.

Enteric Fever

Enteric fever usually is caused by *S. ser. Typhi* and, less often, other invasive *Salmonella*, including *S. ser. Paratyphi* and *S. ser. Choleraesuis*. The onset of symptoms in enteric fever is usually insidious.^{185,186} After an incubation period of 10 to 14 days (range, 6 to 21 days), which generally is related to the inoculum size, fever, malaise, anorexia, and abdominal pain develop over the course of 2 to 3 days. The incubation period tends to be shorter with paratyphoid fever. The temperature rises in small increments, usually reaching 40°C to 40.5°C (104°F to 104.9°F) by the end of the first week of illness. The temperature does not return to normal but rather rises to higher peaks each afternoon, with higher nadirs occurring each subsequent morning during the first week. Eventually the fever is unremitting; spikes in temperature occur without return to normal. In younger children, onset of fever is more abrupt on onset and then could turn intermittent or remain sustained.¹²¹

Constipation occurs in one-fourth of older children and tends to appear later in the course,^{26,210} whereas diarrhea is more frequent in younger children and occurs in more than one-third of patients.^{26,259,373} When diarrhea develops, it is usually after several days of febrile illness²⁰⁹ and tends to be more frequent in children from nonendemic settings, where it can even lead to dehydration.³⁵⁹ It is small in volume and of loose consistency, resembling a greenish pea soup; it contains erythrocytes but usually is not grossly bloody.^{115,259,358} Fecal leukocytes are present in nearly all patients with diarrhea.¹¹⁵ Diarrhea occurs more commonly with paratyphoid than with typhoid fever.³⁷³ Vomiting is mild and not sustained.

A dull, continuous frontal headache begins during the first 2 days of fever and is easier to explore in adolescents.²¹⁰ Children commonly complain of headache and often are drowsy, irritable, or delirious.¹⁰⁶

A relative bradycardia for the degree of fever can be found over the first week, but it is not a constant or specific finding.^{102,368} Patients have a toxic facies; coated tongue; a musty, “damp hay–like” odor; and a tender, doughy abdomen with slight guarding. Occasionally a child may have a low-level cough. The skin is dry with little sweating. Meningismus may occur early in the illness.

During the second week, rose-colored spots measuring 2 to 4 mm may appear on the abdomen or chest and rarely on surrounding locations. They are blanching, erythematous, slightly raised lesions that last approximately 3 days. Rose spots occur in a few patients and are difficult to recognize in dark-skinned individuals. Infrequently, new crops of rose spots continue for 1 to 2 weeks.

A soft, tender spleen becomes palpable by the second week of illness. Respiratory symptoms may progress, and epistaxis occasionally may occur. If left untreated, enteric fever has a prolonged course, with continuous high temperatures of 39.5°C to 40.5°C (103.1°F to 104.9°F) for up to 4 weeks, followed by a gradual return to normal beginning during the third or fourth week. A rapid decrease in temperature late in illness suggests intestinal hemorrhage or perforation⁴⁵; such a decline in temperature typically is followed by an increase a few hours later as peritonitis develops. Intestinal hemorrhage and intestinal perforation^{147,45,61,61} may occur in the second to fourth week in 1% to 3% of patients with typhoid fever.^{26,61}

Complications occur in 10% to 15% of patients; mainly during the second or third week of illness. Many complications, of which gastrointestinal bleeding, intestinal perforation, and typhoid encephalopathy are the most important, have been described (Box 111.2).^{228,291,295} Gastrointestinal bleeding is the most common, occurring in 5% to 10% of patients.^{26,26} It results from erosion of a necrotic Peyer's patch through the wall of an enteric vessel. Suppurative lymphadenitis,²⁷⁸ mesenteric lymphadenitis,^{148,232} tonsillitis,^{197,338} endocarditis,¹¹¹ and pancreatitis^{20,250,412} rarely occur. Patients who have thalassemia or glucose-6-phosphate dehydrogenase deficiency may have hemolysis during typhoid fever.³⁷³

The relapse rate is 5% to 10%, even when appropriate therapy has been given.⁸ Relapses typically occur 2 to 3 weeks after the resolution of fever and are milder than the initial illness. The *Salmonella* isolate from a patient in relapse usually has the same antibiotic susceptibility pattern as the isolate obtained from the patient during the original episode. Reinfection also may occur and can be distinguished from relapse by molecular typing.³⁹⁴

In some geographic areas, such as Indonesia, where an exceptionally virulent *S. ser. Typhi* is endemic, toxemia, delirium, obtundation, coma, and shock sometimes occur.^{228,186,185} Some serotypes in Indonesia (e.g., H1-j) seem to be less virulent than others, suggesting that properties of the flagellar antigen may be important to virulence.¹⁶¹

Typhoid fever varies in its clinical course. Variations on the classic theme include a completely afebrile course occurring in debilitated patients, a high spiking fever from the first day (particularly in children), a focal presentation (e.g., pneumonia and nephritis), and a severe course during relapses. Infants are said to be at higher risk for development of massive hepatomegaly, thrombocytopenia, and other complications.³¹² The mortality rate is high in the neonatal period.³¹⁴ Children younger than 5 years may have a nonspecific illness that is not recognized clinically as typhoid³⁴⁹; infants and toddlers often have a febrile illness misinterpreted as a “viral syndrome.” In children younger than 2 years, the fever may last for only 1 to 5 days, despite the presence of *S. ser. Typhi* or *S. ser. Paratyphi* in the blood; low-grade fever (temperature of 38.3°C–38.8°C [100.9°F–101.8°F]) and cough may be the only findings in such children.^{127,127} Deaths are up to 6 times more frequent in children younger than 5 years compared to older children and adolescents.²⁶ The most important contributor to a poor outcome is probably a delay in instituting effective antibiotic treatment.²⁹⁵

Enteric fever from infection with multidrug resistant *Salmonella ser. Typhi* (MDRST) is found globally in 22% to 25% of children and is more frequently associated with the presence of fever, toxic appearance, hepatomegaly, splenomegaly, and abdominal tenderness and distention on admission in contrast to non-MDRST.^{26,416} Children with MDRST also tend to present later in the course, with current or prior antibiotic treatment, and are more likely have complications such as dehydration, gastrointestinal bleeding, ileus, shock, myocarditis, and/or pneumonia.²⁶

Typhoid and nontyphoid *Salmonella* infections during pregnancy increase the risk for spontaneous abortion.^{266,360} Spontaneous abortion or premature labor usually can be prevented by early treatment.³⁴⁷ Transmission of *S. ser. Typhi* rarely occurs in utero.⁷⁵ Typically premature delivery occurs during the second to fourth week of untreated maternal typhoid fever.¹⁵⁹ In the preantibiotic era, 40% of women with typhoid delivered prematurely; the remainder carried to term, although only 17% of infants survived.¹⁰⁵ If infection occurs late in gestation and is treated appropriately, the infant may survive.

Asymptomatic Chronic Carrier State

Chronic carriers excrete *Salmonella* organisms in stools for longer than 1 year after having gastroenteritis-enterocolitis or enteric fever. Approximately 1% to 4% of patients who recover from enteric fever caused by *S. ser. Typhi* chronically excrete the organism²⁶⁵; fewer than 1% of patients with NTS excrete for a prolonged period.^{59,72} Twenty-five percent of prolonged carriers have no history of typhoid.²⁹⁵ Nontyphoid infection is associated with excretion for a mean of 5 weeks, although children younger than 5 years,⁵⁹ female patients, elderly patients, and patients with biliary tract disease are more likely to become carriers. The biliary tract is infected in almost all chronic carriers of *S. ser. Typhi*. As many as 10⁶ organisms per 1 g of feces may be excreted.²⁶⁵

Chronic excretion in such patients serves as the source of infection to their contacts. Chronic carriers represent an epidemiologically important reservoir of *S. ser. Typhi*; they often are the source of outbreaks of typhoid fever. In the United States, although typhoid fever generally is imported, 30% of infections result from exposure to previously diagnosed or newly diagnosed chronic carriers.³³⁵

Patients who have a history of *Schistosoma haematobium* or tuberculous infections of the urinary tract may develop chronic urinary carriage after a bout of typhoid fever.^{122,321}

DIAGNOSIS

The symptoms in *Salmonella* gastroenteritis overlap sufficiently with symptoms seen in other diarrheal illnesses that laboratory studies generally are required to prove the diagnosis. Proctoscopy is rarely done; typical findings include mucosal edema, hyperemia, friability, and hemorrhages.¹⁰³ The fecal leukocyte examination is positive for polymorphonuclear leukocytes in 36% to 82% of nontyphoid cases,¹⁷⁰ but this finding is nonspecific. Stool culture is preferable to swab culture, particularly for evaluation of long-term carriers. Overnight enrichment in selenite broth increases the yield from stool cultures. The optimal agar for isolation of the organism (SS, Hektoen enteric, MacConkey, xylose-lysine-deoxycholate, xylose-lysine-Tergitol 4, brilliant green, or modified semisolid Rappaport-Vassiliadis medium) is debated. Modified semisolid Rappaport-Vassiliadis medium has a high yield but cannot be used for isolating *S. ser. Typhi* or nonmotile strains and has lower specificity than SS agar.³³¹ Increasing the volume of stool sample improves the yield of *Salmonella* in cultures.³⁹³

Salmonella organisms usually can be isolated readily from blood by use of conventional media if the patient is bacteremic. In patients with extraintestinal focal nontyphoid infection, specimens from the affected areas may have positive Gram stains and grow the organism.

Enteric fever should be suspected on the basis of the setting and clinical course. Laboratory abnormalities are common but nonspecific findings. Normocytic, normochromic anemia and leukopenia or neutropenia, perhaps caused by hemophagocytosis in the bone marrow, often are present.²⁴⁶ Clotting abnormalities consistent with disseminated intravascular coagulation (e.g., thrombocytopenia, hypofibrinogenemia) may occur⁶⁰ but usually are transient and not associated with clinically significant bleeding. In enteric fever, electrolyte values usually are normal, but increases in alkaline phosphatase, serum lactate dehydrogenase, serum aspartate aminotransferase, and serum cholesterol occur frequently. Transient proteinuria sometimes occurs during the first week of enteric fever.

Cultures from multiple sites should be submitted for suspected enteric fever; culture of bone marrow has the highest yield,^{179,181,380} particularly if the patient has had antibiotic pretreatment. During the first week of typhoid fever, approximately 90% of patients have positive blood and bone marrow cultures, but negative stool and urine cultures. During subsequent weeks, the yield of blood and bone marrow cultures decreases as the yield of stool and urine cultures increases. Culture of duodenal fluid obtained by string capsules can be as sensitive as culture of bone marrow aspirates.^{25,181,380} Over the third week of enteric fever, bone marrow culture could remain positive despite negative blood cultures.³⁹⁶ The ratio of nonviable to viable *Salmonella* bacteria in blood ranges from 1000:1 to 47,000:1.³⁰ The overall frequencies of positive cultures during the course of typhoid are found in blood (40–54%), urine

(7–10%), stool (~35%), bone marrow (80–90%), rose spots (~65%), and duodenal string test culture (58–85%).^{149,181}

Blood volume is the most important factor for *Salmonella* isolation in blood cultures, and it is recommended that 10 to 15 mL be drawn per sample from infants, as in adults.⁴⁰⁶ Because bacterial counts in blood are higher in children³⁹³ and the volumes of drawn samples are worrisome both for personnel and caregivers, recommended blood volume for toddlers and infants is 2 to 4 mL.⁴⁰⁶ The Widal test measures antibodies against the O and H antigens of *S. ser. Typhi*. Although many patients with enteric fever may have a fourfold increase in the titer of paired sera during the second week of illness, many false-negative and false-positive test results occur. Widal test titers could rise before clinical onset of disease, preventing the expected fourfold rise in titers of paired sera.²⁹⁸ False-positive results in the Widal test can be caused by infection with other Enterobacteriaceae, malaria, dengue, nontyphoidal *Salmonella*, and other diseases and previous exposure to *Salmonella* antigens (including typhoid vaccines). Variability and poor standardization of commercial test antigens are identified causes for both false-positive and false-negative results.²⁸⁹ Widal test titers may be more useful in children with typhoid who are living in a nonendemic area. Interpretation of Widal test results is aided by information about seropositivity in the population to which the patient belongs.^{82,378} Some centers have found the Widal test helpful when it is used with locally determined cutoff points.^{84,297} The Widal test could be used to diagnose typhoid fever, but only under unfavorable circumstances when no confirmatory microbiologic test result is available; this approach is not to be encouraged.²⁸⁹ Various diagnostic kits, including serologic tests such as passive hemagglutination, passive bacterial agglutination, latex particle agglutination slide tests, counterimmunoelectrophoresis, radioimmunoassay, and enzyme-linked immunosorbent assay with use of monoclonal antibodies, have been developed.¹⁹³ These commercial assays (i.e., Typhidot, Typhidot-M, and Tubex) have not proved to be sufficiently robust in large-scale evaluations in community settings.⁴² Molecular techniques used primarily in epidemiologic studies include DNA hybridization studies, phage typing, chromosome analysis, and plasmid analysis. Recent evaluation of blood culture, typhoid IgM flow assay, and *Salmonella ser. Typhi*/Paratyphi A real-time PCR in children with typhoid fever found typhoid IgM flow assay sensitivity near to that of blood culture (77.9% vs. 80%). However, given that no blood marrow culture was used for comparison, blood culture performance could be overestimated as well as the new IgM flow assay.²⁷⁴ Of interest was the poor performance of real-time PCR sensitivity (37.8%).²⁷⁴

DIFFERENTIAL DIAGNOSIS

Salmonella gastroenteritis cannot be distinguished clinically from other infectious causes of acute diarrhea reliably, although history and epidemiology sometimes may suggest an etiologic agent. Bloody diarrhea with mucus can be caused by *Salmonella*, *Shigella*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, *Campylobacter* spp., *Yersinia enterocolitica*, *Clostridium difficile*, *Trichuris trichiura*, and *Entamoeba histolytica*. Watery diarrhea may be caused by rotavirus or other viral enteropathogens or enterotoxin-producing bacterial pathogens. When abdominal pain and tenderness are severe, the differential diagnosis includes appendicitis, perforated viscus, and mesenteric adenitis.

Enteric fever can mimic other infections of the reticuloendothelial system,⁴³ including Epstein-Barr virus infection, disseminated

histoplasmosis, and tuberculosis, among others (Box 111.3). Noninfectious illnesses with prolonged fever that sometimes can be confused with typhoid include juvenile rheumatoid arthritis and other collagen vascular diseases, Kawasaki syndrome, and lymphomas. An early diagnosis often is difficult to establish because the findings are nonspecific. Findings that are particularly helpful in discriminating typhoid fever from other prolonged febrile illnesses include severe cough and chest pain (more typical of lobar pneumonia), diarrhea with grossly obvious blood (more typical of dysentery), acute onset of chills (more typical of malaria), and marked lower abdominal pain early in the febrile illness (more typical of bacillary dysentery, *Y. enterocolitica* infection, and salpingitis). For patients in countries where typhoid is not endemic, a history of travel is crucial. In endemic developing countries, the widely variable false-positive and false-negative results of the Widal test complicate the differential diagnosis workup, favoring the misuse of antimicrobials.²⁹⁸ *Salmonella* infections could be a cause of fever of unknown origin, especially in developing countries.⁸¹

TREATMENT

For children with salmonellosis for whom antibiotic treatment is appropriate, the interpretation of antimicrobial susceptibility studies is important. Drugs such as aminoglycosides, polymyxins, tetracyclines, and first- and second-generation cephalosporins (e.g., cephalothin, cefazolin, cefuroxime, cefamandole) have a poor clinical track record despite apparent in vitro susceptibility. Table 111.5 shows the drugs that typically are useful in treatment of children with *Salmonella* infections. The emergence and dramatic increase of multidrug-resistant *Salmonella* strains represent an important challenge for empirical antibiotic management.

Gastroenteritis

As with all forms of gastroenteritis, fluid and electrolyte replacement and maintenance are the first objective of management. For most patients, oral rehydration is all that is necessary to treat *Salmonella* gastroenteritis. Generally *Salmonella* gastroenteritis should not be treated with antibiotics because these agents do not shorten the course of illness^{21,23,78,79,207,243,281,302,335} but prolong excretion of *Salmonella*.^{21,23,108,207,281,302} *Salmonella* serotypes typically have been grouped together for these treatment studies, however, as though they were all the same organism. Given the variability in expression of virulence genes, whether treatment may be useful for some serotypes that possess particular virulence traits remains an open question.

Exceptions to the generalization that *Salmonella* gastroenteritis should not be treated include children at high risk for developing complications, including children with underlying diseases or receiving therapies that impair host defenses. Examples of children who probably ought to be given antibiotics are infants 6 months or younger; children with AIDS or malignant diseases; those splenectomized; children with primary immunodeficiencies³⁸; children with chronic hepatopathy; children with hemolytic anemias, particularly sickle-cell anemia; and malnourished children. Treatment of these patients is debatable; the data from neonates suggest that antibiotics make little difference in the course.^{2,118,207,318,365} Because the risk for development of bacteremia is high, however, antibiotics likely will continue to be used in such settings. Bacteremia occurs in a small fraction of infections; therefore, proving the concept is impossible without conducting a massive placebo-controlled clinical trial. When treatment is given, probably 5 days or fewer of antibiotics is indicated, barring complications. Ciprofloxacin or a third-generation cephalosporin (i.e., ceftriaxone or cefotaxime) are recommended in preference to former suggestions in favor of ampicillin or amoxicillin.⁵⁵ Parenteral therapy with a third-generation cephalosporin or fluoroquinolone has been related to reductions in duration of fever and hospitalization in one retrospective study of children with more severe gastroenteritis.³⁷⁷

Extraintestinal Infections

Any child who appears to be sufficiently toxic that bacteremia is suspected also should be started on antibiotic treatment until blood cultures exclude the diagnosis. For children with bacteremic NTS and focal extraintestinal complications, a third-generation cephalosporin (e.g.,

BOX 111.3 Differential Diagnosis of Enteric Fever

Leptospirosis	Disseminated histoplasmosis

TABLE 111.5 Antibiotics Commonly Used in the Treatment of *Salmonella* Infections

Drug	Dose	Comments
Ciprofloxacin	20–30 mg/kg/day in 2 doses PO or IV	First-line therapy ^a
Ceftriaxone	75–100 mg/kg/day in 1 or 2 doses IM or IV	First-line therapy
Cefotaxime	100–300 mg/kg/day in 3–4 doses IM or IV	First-line therapy
Cefixime	20–30 mg/kg/day in 1 or 2 doses PO	Alternative therapy
Azithromycin	10 mg/kg/day in 1 dose PO	Alternative therapy
Chloramphenicol	50–100 mg/kg/day in 4 doses PO	High frequency of resistance; use only for susceptible strains
Ampicillin	200–400 mg/kg/day in 4 doses PO, IM, or IV	High frequency of resistance; use only for susceptible strains
TMP-SMX	10 mg/kg/day TMP, 50 mg/kg/day SMX in 2 doses PO or IV	High frequency of resistance; use only for susceptible strains

^aNot approved by the US Food and Drug Administration in children <18 years; current expert opinion agrees in recommending this agent as an effective therapy for regions with susceptible *Salmonella* strains and especially for severe infections.

TMP-SMX, Trimethoprim-sulfamethoxazole.

ceftriaxone, cefotaxime) or fluoroquinolone is an appropriate choice. If the patient seems to have a life-threatening infection, ampicillin and chloramphenicol should be used only if evidence exists that the pathogen is not resistant to ampicillin or chloramphenicol and that no meningitis or related involvement is suspected. Children at high risk for having recurrence of bacteremia (children with congenital or acquired immunodeficiencies, such as AIDS) may require a third-generation cephalosporin or a fluoroquinolone to achieve cure.^{88,184} Combinations of fluoroquinolones, cephalosporins, and azithromycin are used in patients with severe disease who fail to respond promptly, or in the face of potential drug-resistant strains, or potentially to reduce the emergence of resistant strains during the course of treatment. However there are few studies of the in vitro interactions between antimicrobials for *Salmonella* isolates.⁹⁸ Frequent recurrences of life-threatening infection sometimes necessitate use of prolonged or life-long maintenance therapy with an oral agent, after controlling the episode with prolonged combined parenteral therapy guided by antibiogram results.¹⁸⁴

Many presumed recurrent episodes of NTS in the same child are actually a persistent infection by the same clone in nearly 80% of cases²⁸⁸ and merit evaluation in search of primary or acquired immune deficiencies. In some primary immunodeficiencies, even NTS could elicit fatal hemophagocytic lymphohistiocytosis.^{39,357,371}

Meningitis should be treated with a third-generation cephalosporin because these agents have good penetration into the CSF; ampicillin and chloramphenicol use is associated with higher relapse rates and lower cure rates.^{212,292} Meningitis must be treated for at least 4 to 6 weeks for children with apparent good response;¹⁶ for complicated patients (ventriculitis, hydrocephalus, extensive damage) prolonged therapy of more than 12 weeks could be necessary⁴¹¹; approximately three-fourths of patients who have relapses have been treated for 3 weeks or less.⁸⁶ *Salmonella* may persist for more than 3 weeks inside CSF mononuclear leukocytes despite negative CSF cultures.⁷⁹ Some authors suggest combined antimicrobial therapy with cefotaxime or ceftriaxone plus ciprofloxacin for meningitis.^{74,163,184,292,309} Dexamethasone before or at the time of initiation of antimicrobials, aimed at reducing the severity of sequelae of bacterial meningitis in children, is recommended by extension to *Salmonella* meningitis by some authors^{17,187,411} but available data are very limited and lead to no definitive conclusions.^{271,272,386} Timely initiation of appropriate active bactericidal antimicrobials and severity of disease on arrival are important determinants of outcome, especially in developing countries.¹¹² Moderate to severe sequelae could affect more than half of infants after complete antimicrobial therapy for *Salmonella* meningitis.⁴¹¹ Carbapenems such as imipenem and meropenem have been used with good results in a few cases of *Salmonella* meningitis,^{73,292} but risk for seizures with imipenem therapy must be considered.³⁰⁹ Regarding ceftriaxone effectiveness in contrast to ceftazidime and cefotaxime, data from case series suggest a better response to ceftriaxone, especially compared to ceftazidime.²²⁵

For other extraintestinal infections in children, the duration of antibiotic treatment usually is 10 to 14 days for bacteremia and 4 to 6

weeks for acute osteomyelitis. Collections of pus should be drained, and, for intracranial collections, the total duration of antimicrobial therapy should be extended to 4 to 6 weeks after drainage if this is feasible.⁷³ Nonaccessible collections in the central nervous system need more prolonged therapy and complicate outcomes. Schistosomiasis, when present, must be treated to achieve resolution of the coincident *Salmonella* infection.^{284,321} If combined resistance to all first- and second-line drugs develops, the carbapenems (e.g., imipenem, meropenem, and ertapenem), and tigecycline could be potential alternatives.⁹⁸

Typhoid Fever

The response to antibiotics is slow. Fever may persist for many days, even after bacteremia has resolved.⁴¹⁶ The emergence and spread of MDRST since 1989, defined as combined resistance to chloramphenicol, TMP-SMX, and ampicillin,⁴¹⁶ caused a shift in empirical therapy from once first-line drugs to a fluoroquinolone; a third-generation cephalosporin, such as ceftriaxone; or azithromycin in children (Table 111.6). MDRST is particularly common in the Indian subcontinent, Southeast Asia, and Africa, and resistance to ciprofloxacin is increasing.^{83,327}

In the United States, MDRST has been less problematic than it is elsewhere, but resistance to ampicillin, chloramphenicol, and TMP-SMX has continuously increased since the 1990s.^{4,239,333} Currently most *S. ser. Typhi* isolates are still sensitive to ceftriaxone and ciprofloxacin, although nalidixic acid-resistant isolates are common in travelers returning from the Indian subcontinent.^{4,239} Such strains respond poorly to fluoroquinolones, with a 30-fold chance of requiring retreatment.³⁹⁵ Recent reports from India found 98.9% resistance to nalidixic acid and 75% resistance to ciprofloxacin in *S. ser. Paratyphi A* from 264 blood culture isolates.^{263,395} When the patient has a history of recent travel to or of contact with a traveler from an area with MDRST, the choice of empirical treatment should take this information into account. New minimum inhibitory concentration (MIC) breakpoints have been established for determination of *Salmonella* susceptibility, intermediate sensitivity, or resistance against ciprofloxacin.¹⁸⁹ As a result, MICs of 1 µg/mL or less but 0.06 µg/mL or greater are associated with delayed antimicrobial responses to ciprofloxacin or even to clinical failure.¹⁸⁹ Third-generation cephalosporins are effective against MDRST^{123,193,212,261,275,294,352,374} and appropriate for children in such circumstances. Although older, small trials in adults suggested shorter courses could be comparable to longer courses of treatment, caution is warranted for decisions on treatment duration for children given the low quality of evidence and changing susceptibility patterns over time.⁴⁰⁷ For MDRST in children, ceftriaxone given at 65 mg/kg per day was associated with relapses with short-course therapy (7 days) in contrast to 14 days of therapy.⁴⁴

Current evidence supports ceftriaxone, cefotaxime, azithromycin, and fluoroquinolones as the most effective drugs for the treatment of typhoid fever.^{16,55,407} Fluoroquinolone drugs have proved safe in all age groups, are rapidly effective, and are associated with lower rates of stool carriage than traditional first-line drugs. The three main issues regarding the use of fluoroquinolones are (1) the potential for toxic effects in children, (2) the cost, and (3) the potential emergence of resistance.²⁹⁶

TABLE 111.6 Recommended Antibiotic Treatment of Typhoid Fever

Susceptibility	Antibiotic	Days
Fully susceptible	Chloramphenicol <i>or</i>	14–21
	Amoxicillin <i>or</i>	14
	Trimethoprim-sulfamethoxazole <i>or</i>	14
	Third-generation cephalosporin (e.g., cefixime or ceftriaxone) <i>or</i>	7–10 ^a
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	7–10 ^a
Multidrug-resistant	Azithromycin	5–7
	Third-generation cephalosporin (e.g., cefixime or ceftriaxone) <i>or</i>	7–10 ^a
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	7–10 ^a
	Parenteral third-generation cephalosporin (e.g., ceftriaxone) <i>or</i>	7–10 ^a
Quinolone-resistant	Azithromycin <i>or</i>	5–7 ^a
	Third-generation cephalosporin (e.g., cefixime) <i>or</i>	7–10 ^a
	Parenteral third-generation cephalosporin (e.g., ceftriaxone) <i>or</i>	7–10 ^a

^aFor severe typhoid fever, consider 10–14 days of therapy.

In preclinical testing, the fluoroquinolones damaged the articular cartilage of young beagles. A considerable body of evidence exists supports the safety of fluoroquinolones in the long-term use of these drugs in children with cystic fibrosis and in short-term use to treat typhoid fever and dysentery in children. The availability of generic fluoroquinolones in many developing countries and its subsequent misuse has favored the emergence of fluoroquinolone resistance and marks the greatest limitation on their use.²⁹⁵

In the developed world, described concerns about the toxicity of fluoroquinolones in children have limited their use to situations of MDRST infections with confirmed resistance to all of the usual antibiotics but sensitive to a fluoroquinolone. If a fluoroquinolone is used, ciprofloxacin or ofloxacin is preferred because of better oral bioavailability. Ciprofloxacin 15 mg/kg per dose twice daily for 7 to 10 days in children causes defervescence in an average of 4.2 days, with infrequent relapses, even with MDRST.¹¹ Children with MDRST who have been treated with ciprofloxacin 10 mg/kg per day became afebrile in 3.3 days, and 94% achieved clinical cure, with no relapses or carriers detected on follow-up.¹¹⁶ Ofloxacin is associated with more rapid defervescence and better cure rates than cefixime.⁶³ Very short courses of ofloxacin (2 or 3 days) may be followed by relapse.^{286,390}

Fluoroquinolone treatment for typhoid fever produced lower relapses (relative risk [RR], 0.04–0.52) and length of hospital stay (–3.53 to –1.62 days) in contrast to chloramphenicol.³⁷² Clinical failure (RR, 0.01–0.54) and microbiologic failure (RR, 0.03–0.64) were reduced for fluoroquinolones in contrast to β -lactam antibiotics treatment.³⁷² Fluoroquinolones performed better than third-generation cephalosporins, leading to lower clinical failures and duration of hospital stay.³⁷²

Other agents have been described that occasionally may be useful. Furazolidone 7.5 mg/kg per day is nearly as effective as is chloramphenicol in strains susceptible to both drugs (86% vs. 90% cure).⁸⁶ Despite low serum levels, azithromycin seems to be equivalent to chloramphenicol or ciprofloxacin; the high intracellular concentration in macrophages (>100 times serum levels) of azithromycin presumably accounts for its efficacy.^{62,150,151} When MDRST is resistant to nalidixic acid, azithromycin is more effective than ofloxacin, resulting in faster resolution of fever and very effective control of fecal carriage in contrast to ofloxacin and even to combined therapy of azithromycin with ofloxacin.^{76,296}

A 5-day course of oral azithromycin 20 mg/kg per day (maximum 1000 mg/day) is as effective as intravenous ceftriaxone 75 mg/kg per day (maximum 2.5 g/day for 5 days).¹³⁹ Various non-antimicrobial measures should be considered as part of the management of *S. ser. Typhi* infections.

No good level of evidence exists to establish superiority of fluoroquinolones over first-line antibiotics for typhoid fever specifically in children, but fluoroquinolones are suggested at this time as first-line therapy. Because of the high level of resistance in some regions of the world, the World Health Organization (WHO) recommendations for second-line therapy options include third-generation cephalosporins and azithromycin.⁴⁰⁷

Dexamethasone, although potentially increasing the relapse rate,⁸⁹ is indicated for patients with severe typhoid fever with delirium, stupor, shock, or coma; the dose is 3 mg/kg initially and then eight doses of 1 mg/kg every 6 hours for 48 hours. This therapy reduces mortality rates from 35% to 55%, to 10%.^{180,310} Parenteral fluoroquinolones are probably the antibiotic of choice for severe infections, but no randomized trials of such treatment have been performed.¹¹⁶ Antipyretics were thought at one time to be dangerous in typhoid fever¹¹⁰; whether this concern is correct is doubtful on the basis of more recent experience.²⁸⁷

Intestinal hemorrhage or perforation during enteric fever generally is considered to be an indication for surgical intervention.^{45,61,147,234} Resection of 10 cm of intestine proximal and distal to the perforation seems to improve outcome in contrast to other surgical approaches.²⁴ Antibiotic coverage should be broadened to include anaerobes and gram-negative enterics when perforation occurs.⁴⁵

Chronic Carriers

Generally patients who are not food handlers probably should not be cultured or given special treatment after having a bout of gastroenteritis caused by a NTS strain. Carriers of *S. ser. typhi* should be decolonized to decrease the risk to close contacts. Carriers who have a normal gallbladder can be treated with oral ciprofloxacin or norfloxacin for 4 weeks; these drugs concentrate highly in bile.¹⁶ If oral fluoroquinolone therapy is not tolerated, then high-dose intravenous ampicillin for 4 weeks could be indicated.¹⁶ Other options are oral ampicillin or amoxicillin combined with probenecid for 6 weeks. Chronic carriers who cannot be decolonized are treated with cholecystectomy if cholelithiasis or cholecystitis is present; these patients should receive ampicillin intravenously for 7 to 10 days before and 30 days after cholecystectomy.

PREVENTION

Public Health Measures

Recognition of an increased frequency of human infections with an unusual serotype should be followed by an epidemiologic investigation aimed at detecting the source and vehicle. Intervention to stop such outbreaks then can be attempted. Judicious use of antibiotics in dairy and livestock animals,¹⁸² careful food processing and storage, and proper preparation of foods are helpful in decreasing transmission of infection. Appropriate sewage disposal, assurance of a safe water supply, prevention of sale of pet turtles, inspection of cosmetics for contamination, and adequate cleaning of medical equipment are important public health strategies. Families with small children should be informed of the risks associated with pet reptiles and encouraged to avoid such unnecessary risks.

Personal Hygienic Measures

Person-to-person spread can be decreased by hand washing after defecating or changing diapers, frequent hand washing during preparation of foods that might be contaminated (e.g., meat), and excluding infected individuals from food-handling tasks.

Infection Control

Hospitalized children with *Salmonella* gastroenteritis should be isolated (enteric precautions) until stool cultures are negative. Children with extraintestinal infections should be isolated until stool studies exclude intestinal infection or colonization.

Nursery Outbreaks

Neonatal *Salmonella* infection outbreaks should be investigated to determine the source. Cultures of fomites sometimes reveal a removable focus. Neonates and staff members caring for them should be cohorted during outbreaks, with use of enteric precautions in dealing with infants

who are excreting the organism. Surveillance cultures should be done on feces of not only sick infants but also well infants to cohort more appropriately. With current early postpartum discharge policies, reporting *Salmonella* infections in infants is important in detecting outbreaks. Isolation and cohorting can be effective in controlling such outbreaks.³¹⁷

Breast-Feeding

In the developing world, breast-feeding is key in prevention because human milk contains secretory IgA and other factors that protect infants from *Salmonella* spp.^{14,52,124,125,138,305,306} Case-control studies conducted in the United States and Australia also found breast-feeding to have a strong protective effect against sporadic *Salmonella* infections.^{326,402} Pediatric health care providers and community education programs should encourage mothers to breast-feed.

Vaccination

Vaccination of children is indicated when the risk for development of typhoid fever is high (e.g., living with a chronic carrier or in an endemic area) but probably is underused.^{356,370} Only 4% of U.S. travelers to endemic settings who acquired enteric fever were previously vaccinated.³⁵⁶ An updated position paper from the WHO on typhoid vaccine policy recommendations is under development.⁴⁰⁹ Two vaccines are extensively available: (1) an oral live attenuated Ty21a vaccine (Vivotif Berna) and (2) a parenteral purified Vi capsular polysaccharide vaccine (Typhim Vi).^{214,307}

The Ty21a vaccine has been evaluated in liquid and capsule forms. Ty21a oral vaccine is well tolerated; abdominal pain, nausea, vomiting, and rashes occur rarely. The form licensed in the United States is an enteric-coated capsule preparation meant to be given in four separate doses on alternate days and taken 1 hour before meals. It is not recommended for children younger than 6 years. The four doses should be completed 1 week before potential exposure.¹⁶ Revaccination with the entire four-dose series is recommended every 5 to 7 years in high-risk settings. Because the Ty21a oral vaccine is a live-attenuated *Salmonella*, it should not be used in immunocompromised hosts or in individuals taking antibiotics at the time of vaccination.^{16,63,194} Mefloquine, chloroquine, and any combination of atovaquone/proguanil and pyrimethamine/sulfadoxine can be administered together with Ty21a vaccine only if given at doses for malaria prophylaxis.¹⁹⁴ Proguanil use other than prophylaxis must be delayed after 10 days from receipt of the fourth dose of Ty21a vaccine.¹⁶ Other antimalarial drugs could be given 3 days after the last Ty21a vaccine dose.¹⁹⁴

Several large field trials suggest that the Vi capsular vaccine as a single 25- μ g dose (0.5 mL) has an efficacy of 55% and 75% in adults and children older than 5 years, respectively.^{3,307} Although fever, malaise, local pain, and tenderness occur with this vaccine, it has two major advantages over the Ty21a oral vaccines. It does not require refrigeration, and only a single dose is required for protection; it is repeated every 3 years.⁴⁰⁸ It may be used in children 2 years of age. Vaccination must occur at least 2 weeks before exposure.¹⁶

Two parenteral Vi vaccines conjugated with tetanus toxoid are licensed and produced in India (PedaTyph and Typbar-TCV).^{268,385} The first dose of PedaTyph is advised for subjects older than 2 years of age, followed by a second dose at 4- to 8-week intervals, and then by a booster every 10 years.²²⁹ Only the Typbar-TCV vaccine is recommended by the Indian Academy of Pediatrics (IAP), to be given as a first dose to infants 9 to 12 months old followed by a booster dose at 2 years of age. There should be at least a 4-week interval between Typbar-TCV and any MMR vaccine dose due to paucity of data regarding any possible interference between these vaccines.³⁸⁵ The IAP has urged the Indian government to recommend universal typhoid immunization.³⁸⁵ Several vaccine producers from Asia, Russia, and Cuba manufacture local-use parenteral polysaccharide Vi vaccines.²²⁹ Typhoid vaccination is recommended additionally for curtailing typhoid fever outbreaks.⁴⁰⁸

PROGNOSIS

Salmonella gastroenteritis usually is a self-limited disease in the normal host, although chronic diarrhea sometimes develops after an acute episode. Extraintestinal focal infections with nontyphoidal *Salmonella*

strains are difficult to cure, particularly if they involve the meninges or occur in compromised hosts. *Salmonella* spp. meningitis may relapse if the course of treatment is too short. Likewise, bacteremia and focal infection recur after treatment in severely compromised hosts, particularly patients with AIDS. Relapse after typhoid fever has long been recognized as a risk.
